# A VALUABLE FOOD BISCUIT

## MACFARLANE LANG & CO.'S

### DINNER TOAST

The DINNER TOAST biscuit, the 1a addition to our series of Food Biscuits composed of the finest wheaten flour, p butter, malt and milk, contains but a trif percentage of moisture, and makes a cr crusty appeal to the palate.

Primarily it has been introduced persons of dyspeptic tendencies who cannot partake of ordinary bread or toast with comfort. For such, the DINNER TOAST BISCUIT, both from the standpoint of EASE OF DIGESTION AND HIGH CALORIC VALUE, provides an excellent substitute.

Taken also with a glass of milk, a cup of beef-tea or other nutritive fluid, the DINNER TOAST biscuit makes a sustaining emergency meal.

*Send a postcard for Sample to*

medically over long periods; and the epithelioma of the hands in x-ray operators. These and several others seem to show a very intimate relation between particular irritants and tumour formation, but several considerations have long stood in the way of establishing a direct causal connection between them.

Comparatively few of the subjects exposed to the action of soot, tar, paraffin, aniline dyes, and the rest develop malignant tumours; even those who become affected have been in contact with the noxious substances for many years; more arresting still is the fact that several of these workers have retired from such occupations and yet, years afterwards, have developed the same peculiarly localized cancers. Considering, too, the numerous instances of malignancy supervening on other chronic lesions, and the fact that the so-called irritation cancers are so rare in comparison with the large numbers of tumours arising without the intervention of any known or suspected irritant, we have had to admit that our carcinogenic agents might only be the mediators and not the proximate causal factors of the disease. All that we could claim for them was that they brought about a pathological state of the tissues, on which prepared soil the undetermined cancer germ or virus or influence might then exert its action.

Sometimes, however, the progression of events was so uninterrupted—as, for example, in arsenic cancer, where any particular time when one factor could give place to another. No one had ever produced cancer experimentally by the use of any of the implicated irritants. Of course, numerous claims to have done so by the injection of this or that parasite have been put forward. Let us not resurrect them. The silent records, too, of our laboratories contain many a failure that we have not liked to parade. But a new era dawned on cancer research when Johannes Fibiger of Copenhagen presented his brilliant experiments on the production of gastric cancer in rats. Then for the first time could it be said that cancer had been produced experimentally beyond all doubt, and explorations into the etiology of cancer became practical problems.

## SPONTANEOUS CANCERS.

While examining the bodies of three rats that had been inoculated with tubercle bacilli Fibiger found in each case a cancer of the fundus of the stomach. Such a thing had never before been seen in the rat, though scores of thousands of these animals had been examined for tumours. Malignant new growths do exist in rats, about once in a thousand cases, but cancer of the stomach had never been observed. Fibiger at once endeavoured to propagate the tumours by inoculation of fragments into other rats, and failed. Fresh rats were fed with other pieces of the tumour; nothing happened. Another hatch was put in the cages previously occupied by the infected rats, they remained unaffected. Microscopic investigation of the gastric tumours showed them to be epitheliomata, for the capsule half of the rat stomach is lined with squamous epithelium, and amongst the epithelial cell masses there were round spaces sometimes containing a few minute structures that suggested sections of an animal parasite. Fibiger

relatively few which are definitely pathogenic. These specific irritants, or carcinogenic agents, as far as we know them, require a prolonged time to work their effects, and they appear to be selective in that certain animal species, certain strains, certain individuals, and certain tissues only are vulnerable to their operation. In the human subject we have the well known instances of the cancer of the scrotum to which chimney-sweeps and labourers in the tar, pitch, and paraffin industries are especially prone; the cancer of the urinary bladder in dyeworkers and in the victims of bilharzias; the epithelioma of the abdomen and thighs in natives of Kashmir; the multiple skin cancers in those who have taken arsenic

just as out of the myriads of kinds of bacteria there are call tissue are capable of inducing tumour growth, point that that few of the substances which we might the evidence. Probably we shall find our experiments the production of cancer. His was a theory that anticipated agents that we now know to be closely associated with the nature, not further defining or particularizing, for there tumours were caused by irritation of a chemical or physical

Victor, the father of modern pathology, contended that not less nebulous, a similar wide-embracing robe? irritating and acrid properties of the black bile. Are there cancer, as well as many other diseases, was due to the them all. The ancient Greek physicians imagined that long-continued irritation. That is the oldest theory of and the recent experimental investigations have been born theory, we cannot wholly dispense with working hypotheses, property of our knowledge, to avoid bound alligance to any of the truth. Anxious as we should be, in view of the present adopt the dialectical strategy of Hegel and say much experience carefully interpreted, we may for the for the theories of the greater thinkers, the outcome of scarcely a breath of criticism for their destruction; and as The gossamer fancies of the armchair philosopher need cancer has so long held its sterile and unproductive way. is little wonder that speculation regarding the causation of tumour growths, and with their antecedents so obscure, it

\*Delivered before the Nottingham Division of the British Medical Association, January 25th, 1922. From *Reports of a tumour, simple or malignant, and carcinoma, to produce. Such subjects as carcinogenic, cancerous, and cancerogenic, which have been used by others, are hybrids to be avoided.*

these through hundreds of serial sections, and reconstructing the pictures, he found he was dealing with a nematode, and subsequent dissection of a preserved portion of the tumour enabled him to obtain an entire worm of a species hitherto unknown, to which he afterwards gave the name of *Spiroptera neoplastica*.

Observe the conjunction of facts: three rats in one batch, each with cancer of the stomach and in each tumour the same parasites; cancer of the rat's stomach never seen before; a nematode till then unknown. What was the relation between the nematodes and the tumours? A mere accidental coincidence, many would have said, and dismissed it. A probable predisposing cause in these particular cases would have been accepted by the majority. Had Fibiger stopped there he would have made merely an interesting contribution to the literature of our subject, and cancer research might still be the fettered Andromeda of pathology. He killed and examined carefully over a thousand rats, but failed to find either a gastric lesion of any importance or the particular nematode he sought for. Reading the literature of animal parasites, he learned that Galeb had been able to obtain nematodes in the stomach of some rats by feeding them on the common cockroach, *Periplaneta orientalis*, which was infested with another stage in the life cycle of these parasites, and thinking this might be a possible clue he examined rats from a locality in Copenhagen where such cockroaches abounded, but without success. Then he fed fresh laboratory rats on these cockroaches, and again nothing resulted. But finally, when the sustaining hope was almost gone, he heard of a large sugar refinery in the town, where both rats and cockroaches swarmed. The cockroaches here were of a different kind; they were *P. americana*, uncommon in Northern Europe. An examination of the rats revealed many cases of gastric tumours, and in them the long-sought-for nematode was found. A false clue, and a stroke of fortune that was bravely deserved, led him to the great discovery. These cockroaches had come in consignments of sugar from the West Indies; in their muscles were the coiled-up larvae of the nematode, and when the cockroaches were eaten by the rat the larvae were set free and developed in the stomach into the adult nematode. Here, after a time, it produced eggs, which were evacuated with the faeces, eaten by the cockroach, and the larval stage again produced, and so the cycle went on. By feeding other species of cockroaches on the eggs Fibiger succeeded in getting these to serve as intermediary hosts, and thus he obtained his source of supply of spiropterae. By feeding laboratory rats on such artificially infested cockroaches, or on the larvae isolated from their muscles, he induced gastric epithelioma in over 50 per cent. of them.

The freed larva burrows superficially in the gastric epithelium, and there develops to maturity. In some cases no change takes place in the stomach, but in most instances the epithelium begins to proliferate and forms papillomatous projections, and sooner or later the proliferating cells penetrate the muscular coats and reach the peritoneal covering. The nematode may also lodge in the epithelium of the tongue, producing glossitis, leucoplakia, and finally cancer. Strangely enough, though the worms may inhabit the oesophagus they have never been found to induce more than papillary hyperplasia in that situation. In no other portion of the alimentary tract do the parasites lodge or produce neoplasms. Metastases have occurred in several cases in the lungs or lymphatic glands, but from these secondary tumours the parasites were absent. Having once started malignant proliferation, probably by the prolonged toxic action of some excretion, the parasites are no longer essential to the continued growth of the tumour. The parasite may be transferred to wild rats and to other rodents, but in no case has cancer resulted. There are thus species, strains, and particular tissues which are insusceptible to the action of the nematode. Mice are relatively insusceptible, only about 5 per cent. developing gastric tumours; but whilst cancer may be produced in rats in six weeks to three months it takes many months—perhaps over a year—to induce it in mice.

I have given the merest outline of Fibiger's researches—epoch-making, patiently pursued, and brilliantly executed. He was the first to furnish us with a means of producing

cancer experimentally at will with a definite agent. He is the pioneer in the experimental inquiry into the etiology of cancer, and I should like, as a humble follower, to pay him my tribute. To my mind, Fibiger's work has been the greatest contribution to experimental medicine in our generation. He has built into the growing structure of truth, something outstanding, something immortal, *quod non imber edax possit diruere*.

#### CYSTICERCUS SARCOMA.

The greatness of Fibiger's achievement stands out in relief when we reflect on the mass of information we had at our disposal regarding another and commoner parasite which is associated with tumour formation, and which, had our eyes been alight, we might have utilized. In examining the bodies of laboratory rats it is no uncommon thing to find cysts of the liver, sometimes single, sometimes in large numbers, filled with clear mucoid fluid and containing a triangular-headed parasite with flattened segmented body—the *Cysticercus fasciolaris*, the larval stage of the *Taenia crassicolis* which affects the cat. Less frequently these cysts may be situated in the omentum, kidneys, or other abdominal organs. Several observers, notably Borrel in 1906, Regaud in 1907, Bridré in 1909, and McCoy in the same year, had described sarcoma of the liver of rats occurring around these parasitic cysts. Bullock and Rohdenburg in America made careful histological studies of several such sarcomata. Histologically the tumours are all of the same nature—spindle-cell sarcomata often highly vascular with a tendency to the formation of large multinucleated cells—and they arise from one or more parts of the compressed connective tissue constituting the wall of the cysts. Borrel and others were able to transplant these sarcomata, and there is no doubt about their true nature.

There are several highly suggestive features about these tumours. Of all the cases of tumours that have been reported in rats, well over a hundred in number, no less than four-fifths have been sarcomata; more than half of these sarcomata have been situated in the liver; and there they have practically always been found around a cysticercus-containing cyst. But it was not until 1917 that any attempt was made to produce sarcoma experimentally by means of the worms. In that year, when reporting a spontaneous case, Hirschfeld, instigated undoubtedly by Fibiger's work, stated that he had instituted feeding experiments on rats with the ova of *Taenia crassicolis*, but as no later communication on the subject came from this author's pen we may assume that his experiments failed. Bullock and Rohdenburg in 1920 were successful. To a very large number of rats they administered by mouth on a single occasion the ova of the adult worm obtained from the faeces of an infested cat. Certain strains of rats, and especially old rats, proved quite insusceptible, but in the majority of young rats the larvae reached the liver and formed cysts, and in about a quarter of the number of such animals sarcoma developed on the cyst wall. Usually only one sarcoma was produced, though there might be dozens of cysts, but in a few cases two independent sarcomata were found. Metastases occurred in about 60 per cent. of the cases. There is a long latent period in the development of these liver sarcomata—eight to fifteen months or more elapse after the ingestion of the ova before the sarcoma starts, but once started it develops with great rapidity. This peculiar feature in the experimental production of sarcoma—the prolonged latent period followed by explosive growth—has struck me in my experiments with paraffin oils and has been noted by Russell in his tar experiments on rats. Possibly we may find it characteristic of sarcoma in general.

Schmidt-Jensen of Copenhagen has failed to produce cysticercus sarcoma in rats, so that there are probably strains of rats that are refractory to this tumour-producing agent. It is presumed that the toxic products of the cysticercus furnish the necessary constant tissue irritant; but however, that be, a susceptible tissue is required. The same parasite is commonly found in the liver of mice, but sarcoma of the liver has never been reported in the mouse save in one doubtful case, and neither in that nor in the epithelial tumours of the liver, some thirty in number, could any parasite be discovered.

insoluble substance, produce its harmful effects on the exposed skin? By dissolving pitch in human sebaceous fat I have produced malignant tumours in mice in less than three months. On the other hand, I have applied Scottish blast-furnace tar, which is produced at a comparatively low temperature, to mice for eight months without obtaining any sign of tumour formation. Tars are found to vary considerably. Thus we applied a direct ethereal extract of a tar to 500 mice, with the result that at the end of five weeks, so toxic was the extract, only 26 remained alive. As it was useless to continue we stopped the applications, but in one case a tumour appeared in the record time of thirty-seven days. It and several others which subsequently appeared became malignant. Using the same extract of another tar from the same gasworks we found no such toxic action, and the earliest tumour took nearly three months of repeated applications to declare itself. Kennaway's experiments are of practical importance because means may be found in the industries concerned to obviate the necessity of exposing men to dangerous distillation products of tar, and thus to prevent a certain number of cases of cancer.

Deelman of Amsterdam has discovered that if the tar applications are preceded four or five times by light scarification of the skin tumours result in the second month. Apart from this demonstration that the superficial layers of the epithelium act as fairly efficient barriers against the irritant, it seems to me that his experiments open up suggestive paths for the investigation of the relation between the processes of wound repair and malignant proliferation.

Murray has recently made a contribution which may have far-reaching results. He found that if he extirpated a tar epithelioma and then resumed the tar applications he could not induce any subsequent tumour formation in that animal. Further, if he removed a spontaneous tumour from a mouse and subjected that mouse afterwards to tar paintings it did not show any neoplastic response to the tar. In view of the fact that two different cancers are of very rare occurrence in the same individual, and, judging from statistics, much rarer than the laws of chance would indicate, he argues that the occurrence of one form of cancer in an individual protects the body in some way against the occurrence of another. The practical application of this must be obvious. There is, however, room for some difference of interpretation of the facts, and more extensive experiments may modify the conclusions that one is tempted to draw from these important observations.

I cannot here touch on numerous other observations by ourselves and other workers—the analyses of precancerous states, the reactions of defence, or the questions of immunity and susceptibility. Though of interest from the theoretical point of view, their practical bearing is not yet of general interest.

#### CHIMNEY-SWEEPS' CANCER.

It is now nearly 150 years since Percivall Pott called attention to the chimney-sweeps' cancer of the scrotum. Not only was this the first time that any tumour formation was attributed to a definitely ascertained irritant, but, still more important, it was the earliest recognition of the purely local origin of a cancer; as Pott said, it was not a "disease of the habit." Since his time numerous English authors have written on the disease without adding much to the classic description. Frequently they have remarked on the increasing rarity of this form of cancer, to the wider recognition of the v... .. amongst sweeps. In point of fact, it is probably as common to-day as it was then. The English mortality returns give a yearly average of five or six cases. There are two features about this cancer that merit attention: (1) its geographical distribution, and (2) its exclusive localization to the scrotum.

It is practically unknown on the Continent. By the courtesy of the Registrars-General of Ireland and of Scotland I gather that it is relatively common in the former country, and so rare in the latter that several years may elapse between cases. In their recent paper Southam and Wilson state that of 141 cases of cancer of the scrotum admitted to the Manchester Royal Infirmary

during the last twenty years only one was a chimney-sweep. Thirty years ago Butlin dealt fairly exhaustively with the question why the disease was so common in England and so rare on the Continent, concluding that the greater protection in the matter of clothing in the case of the foreign sweeps and the different methods adopted abroad in the use of domestic coal accounted for the contrast. But no such explanation can account for the unequal distribution of the disease through the British Isles. It is well appreciated in industrial concerns that coals from different localities have their well marked characteristics; even in the same pit and the same seam coals of different composition exist. The tars obtained by the destructive distillation of different coals vary very much, and this holds good with regard to the pitches. Chimney-sweeps, whom I have questioned on the matter, claim to be able to identify the particular kind of soot which is most dangerous, though they do not agree in their description of its physical appearances. I suggest that the soot which contains the tumour-producing substances is derived from the more bituminous coals coming from the Midlands of England.

But even more mysterious is the fact that soot cancer in chimney-sweeps is confined to the scrotum. That one or two cases of epithelioma arising in other situations have been reported in workmen engaged in the handling of soot does not affect the general statement. Other parts of the body in sweeps are as much exposed as the scrotum, probably more exposed, to the action of the soot, and though occasionally soot warts may be found on the skin at other places, the scrotum is the seat of election of the epithelioma. The same thing holds to a lesser extent in the cases of pitch and paraffin cancer. Why should this be so? The laxity of the scrotal skin, enabling the soot to lodge in its folds, as suggested originally by Pott, seems to offer only a partial explanation. One peculiarity has hitherto escaped attention. The scrotum in the human subject contains unusually large sebaceous crypts, which are not infrequently rendered prominent by the retention of inspissated secretion. I imagine that the soot may lodge there, and that the carcinogenic principle it contains is abstracted and dissolved in the sebaceous fat.

For years experimenters have endeavoured to produce cancer in animals by means of soot, but without success. I have rubbed soot into the scrotum of rabbits (in which animals, be it noted, the scrotal skin is lax and rugose) thrice weekly for two years; I applied it to the scrotum of rats for a year; and I had batches of male mice living in boxes of soot for several months; but in no case did I succeed in producing any perceptible lesion of the epithelium. It may be that I was unfortunate in not having the right kind of soot, but I am more inclined to the belief that the natural solvent necessary is absent from the scrotum of these animals. Passey induced epithelioma in mice by painting on their backs an ethereal extract of soot. His experiments are valuable in demonstrating that soot does contain a tumour-producing fraction to which mice at least are susceptible, but it is obvious that in the animal body we have no such powerful solvent at work. To supply the natural solvent which I fancy is present in the human scrotum and absent or deficient in the scrotum of laboratory animals, I have had recourse to the sebaceous fat from ovarian dermoid cysts. I have to thank numerous gynaecologist friends for supplies of ovarian dermoids. Different samples of this fat vary a little, but they are all liquid at about body temperature, and they dissolve some fraction of soot, the melting point of the solution being lower than that of pure fat. The experiments with this solution have not proceeded far enough to forecast the result. I have already mentioned that with this sebaceous fat as a solvent for the active ingredients of pitch I have readily produced malignant tumours in mice.

#### PARAFFIN CANCER.

It has been known for fifty years that workmen exposed to the action of the crude products obtained by distillation of the oil-bearing shales of Scotland and of the brown coal (lignite) of Germany are prone to develop chronic skin affections, papillomata and epitheliomata, especially on the arms and not infrequently on the scrotum. The most

whilst others have maintained that they are due to the products of combustion of the tobacco. Still others have supposed that the noxious principles exist as such in the unsmoked tobacco and are not produced during combustion. In favour of this last idea are cited instances of malignant growths of the oral mucous membrane in tobacco-chewers, and much attention has been directed to the cancers of the cheek observed in natives of Southern India and the Philippines who chew "betel." Here, however, it must be noted that the betel preparation is a crude mixture of areca leaves, lime, and probably other substances as well as tobacco, and the effect of these accessories cannot be discounted. That betel-chewing is indulged in by millions—men, women, and children—and that the number of cases of cancer of the cheek actually observed by any one medical man seem to be surprisingly few, are points that should make us cautious in accepting this as an instance of cancer due to tobacco, or even as an example of an irritation cancer at all. Again, not a few surgeons of great experience in lingual cancer have stated that tobacco-smoking is of quite subsidiary importance in producing the lesions which, in their opinion, are the sequelae if not the result of local tertiary syphilitic infections.

I need not discuss the arguments at length, for the discussion would be as fruitless as the arguments are interminable. Can experiment help us to settle the question? I must leave aside, as too difficult of approach at present, the test of heat, syphilitic infection, and other general irritations, merely remarking that Fibiger succeeded in producing leucoplakia and epithelioma in the tongue of the rat by an animal parasite (*S. neoplastica*), and record the results with tobacco. We set up an artificial pipe where the tobacco was smoked by suction from a water pump and collected the fluid products of combustion, such as are found in the stem of an ordinary pipe. These products consisted of a brown tarry material easily soluble in chloroform or ether, and a light-coloured watery fluid which darkened through time or by oxidation. The latter fraction, tested on mice for over a year, was without toxic properties and produced no pathological effects whatever. The chloroform-soluble fraction, with the solvent driven off, had, on the other hand, both toxic and pathogenic properties. A minute trace of it applied to the mucous membrane of the tongue or of the vagina, or even to the skin, of rats and mice brought about death by clonic convulsions, usually within a minute. This poisonous effect is probably due to nicotine. By diluting the tarry fraction with acetone to 5 per cent. and afterwards gradually increasing the concentration we found that we could accustom the mice finally to the undiluted stuff. Again, we boiled the tobacco in water first of all in order to deprive it of nicotine and obtained a non-toxic product by smoking. We applied these fractions to two series of mice for many months. They produced epilation of the areas to which they were applied, and they induced chronic ulcerations, but in no single case did any neoplastic reaction result. We have thus no evidence in support of the contention that tobacco smoke contains a cancer-producing property, though we may not therefore conclusively reject the idea that there is something connected with tobacco-smoking which may be operative on the oral mucous membrane of human beings. But what is of more theoretical and practical interest is the fact that here we had a substance with a very marked irritative effect on the skin in that it produced chronic lesions and yet no tumour formation supervened. We might say that it is not a specific irritant of the tumour-producing class.

#### ANILINE CANCER.

In the German literature much has been made of the occurrence of tumours of the urinary bladder in workmen engaged in the manufacture of aniline dyes. Though we have insufficient data to allow us to say that the incidence of bladder cancer amongst them is much greater than in the general population, the reports of its absolute frequency lead us to regard it as a particular form of cancer to which dye workers are liable—an irritation cancer of a different kind from what we have been considering. No cases have been known to occur in English dyeworks. There is no general agreement amongst the authors as to the particular chemical substance responsible for the condition, and an analysis of the reported cases with reference to the process

in which the men were employed fails to reveal any definite clue. In one factory the greater number of cases may occur in the aniline department, in another the fuchsin workers would seem to suffer most, and so on. To complicate matters still further, cases have been noted in clerks and others who do not come directly into contact with any of the processes. This has led to the belief that it is something in the atmosphere. Miss Alice Hamilton, the American authority on industrial diseases, has suggested that the particular noxious substance is hydrogen arsenide, but the German experts strenuously deny that this is present in their workshops, and, as far as I know, no case of so-called aniline bladder cancer has exhibited the usual skin changes that are found in arsenic workers. Aniline, benzidine, and fuchsin are the main products that have come under suspicion. Inhaled, or absorbed through the skin, they undergo probably very complex changes in the economy, and are excreted in different combinations in the urine. It is imagined that the long-continued action of low concentrations of these end-products, whatever they may be, on the epithelium of the bladder induces villous papilloma and finally epithelioma. No other tissue of the body responds in this way to the aniline derivative: it is definitely selective in its action; indeed, the kidneys and ureters, equally exposed to it, do not show tumour formations.

If we could produce cancer of the urinary bladder in animals by applying some aniline product to the skin we would succeed in carrying our experimental inquiry to a more important stage than it has yet reached; it would enable us to demonstrate clearly the selectivity of a carcinogenic agent. So far we have given a prolonged trial to aniline, benzidine, and fuchsin, applied to the skin of mice, but in no case have we produced any neoplastic response either in the bladder or elsewhere. We have also kept series of mice for a long time on xylene and benzene, the precursors of most of the aniline substances, but here also we have failed to induce tumours. Everybody knows the irritating effect of xylol on the skin. In the case of mice its long-continued application produces epilation and that chronic scurfy dermatitis which we generally find with all the tumour-producing agents we have hitherto employed. In several cases, after the lapse of several months, we obtained what we thought were flat warts of a non-progressive character. The histological examination of these, however, showed us that there was no epithelial proliferation but merely a peculiar vitreous degeneration of the tissues of the dermis. Though the experiments, therefore, are negative as far as tumour production is concerned, and leave the question of aniline cancer as undecided as before, those with xylol especially are of value in indicating once more that all tissue irritants have not the property of setting up, or paving the way to, cancer.

#### OTHER SUBSTANCES.

In addition to those I have mentioned we have tried a large number of substances which might be supposed to have an irritant action on the tissues, but they have proved altogether incapable of producing tumour formation. Thus we may tentatively claim that there are only certain specific agents which have the property of eliciting neoplastic reactions. We hope in the course of time to discover more. It will not escape notice that in all the cases in which we have succeeded in producing tumours experimentally, these tumours, epithelioma or sarcoma, are of the same structure whatever substance we employed to produce them. No one examining the final lesion could say what particular agent we used. And it might be maintained as strongly as before that some single common cause must be postulated. It does not follow. Similar acute or chronic inflammations may be caused by very different bacteria.

I must leave to some future occasion the argumentation regarding these disputed points, but even supposing our contentions that some of the substances above mentioned are direct causes of cancer be admitted, it might yet rightly be urged that they are all external irritants, that they are responsible only for a very small number of cases of cancer in the human subject, and that we have thrown no light whatever on the processes that occur within the cells to pervert them to the anarchic and progressive proliferation that we call cancer. We may reply that the demonstration that

has already been given tempt us to hope that some day we shall be able to isolate endogenous carcinogenic substances, local metabolites of metabolism it may be, which have similar effects on tissues long subjected to their action. It is true that we know nothing regarding the intimate cell processes that are set up by the irritants, but the investigation is not beyond practical methods of inquiry. I recall some old experiments that I did several years ago? I had a transplantable mouse carcinoma which had passed into a depressed phase: the percentage of successful inoculations was very low; when tumours did result they were very slow in their growth. I ground up some of the tumour material in fine sand in a mortar and shook this up with saline solution. A batch of mice were injected with this extract and subsequently they were inoculated subcutaneously with living tumour tissue at the same time as another untreated series of mice. The contrast between the two sets was striking: in the untreated series the proportion of successful inoculations was small and the tumours were slow in developing; in those previously treated with the extract the percentage of successful inoculations rose from 50 to 80 and the rate of growth was rapid. We had supplied to the controls, and we had obtained it from the same tumour tissue. Such a substance, whatever its nature may prove to be, may be produced in small amounts in ordinary wound repair: it may be produced in excessive amounts in the neoplastic reaction.

Looking back on the great discoveries of the past, we may wonder why they were so long delayed. The essential data for a conclusion, the materials with which to build, the terrain for the advance, all were already prepared, available for everybody, and sufficiently obvious, we should imagine, to the ordinary mind. It is all so simple to us now, for we fail to appreciate the difficulties of the pioneer. A future generation, knowing surely the causes of cancer, will have no patience with our bouding, our guesses, and our contending arguments. Had we not all the facts before us, they will say, starting us in the face, clamouring for recognition? Probably we have, but we are like children gazing at a starry sky—the stars that are so bright to us may be very small worlds and those that we barely see may be infinitely great. When we can place our facts in their order of importance, and make order out of seeming disorder, the answer will be easy. At present do we stand in respect to our subject as our predecessors stood fifty years ago at the dawn of bacteriology, and as epoch-making as theirs? I wonder.

## SURGERY OF THE HEPATIC AND COMMON BILE DUCTS.

WILLIAM J. MAYO, F.A.C.S., HON. F.R.C.S.

(FAC. AND INC.)

SURGEON TO ST. MARY'S HOSPITAL, ROCHESTER, MINNESOTA.

The great bile duct as a whole, from the point where the hepatic duct emerges from the liver to the duodenal papilla, is discussed because the pathologic processes within which the surgeon is concerned in this special field must be treated as a whole.

In the period from December 31st, 1880, to December 31st, 1922, there were 16,980 operations performed on the biliary tract for all conditions—acute, chronic, and malignant—by the eleven surgeons on the general staff of the Mayo Clinic, with an average mortality of 2.6 per cent. Of these operations 1,920 were on the hepatic and common ducts, with an average mortality of 7.8 per cent.

In the ten years from 1910 to 1920 the average mortality for operations on the great bile duct was 6.8 per cent. In 1921 the mortality for operations on the common and hepatic ducts was 5.6 per cent, in 1922 it had dropped to 3.8 per cent, while in 1922, for 942 cholecystectomies, it was 1.6 per cent.

Important experiments in tissue culture which are being carried out by A. H. Drew of the Imperial Cancer Research Fund may have an important bearing on these points. Abstract of paper read before the Surgical Section of the Royal Society of Medicine, London, June 27th, 1923.

The question of post-operative disability is important. A surgical procedure should be planned so that the patient, with the least possible risk and loss of time, will receive the greatest possible benefit. To-day industry is on a full-time basis, and every unnecessary day that the patient is disabled is an economic loss. To perform several operations when one would suffice, and thus deduce an apparatus but not a true reduction in mortality, to use a type of incision not strictly indicated for the work at hand, or to use unnecessary drainage which will confine the patient to bed longer, or leave him with a greater hernia liability, is unjust. This economic loss is illustrated by a comparison, at ten-year intervals, of the hospital morbidity following operations on the biliary tract. The methods in use to-day, as compared with methods used ten years ago, save for each patient operated on in the clinic ten days of hospital time, or thirty-six years of the lifetime of one person each year. The incision used in the majority of operations on the biliary passages has been the incision introduced by Deaver in 1898, slightly modified. The method of Alexander, leaving undivided the posterior aponeurosis, the peritoneum, and the nerves in the lower third of the incision, is followed because the posterior aponeurosis, peritoneum, and nerves are sufficiently mobile to be drawn down readily by a retractor.

Secondary operations on the common duct for the removal of a retractor.

We study surgical tragedies and endeavour in every way to hold operative mortality at the lowest point, but the mere fact that a patient recovers from an operation is not in itself sufficient. If he does not receive sufficient benefit to warrant the risk of life, the pain and suffering from the operation itself, the expense, and the loss of time, he has just cause for dissatisfaction. On the other hand, if a more radical operation would have resulted in corresponding greater benefit, an increase of primary risk might be justified.

The question of post-operative disability is important. A surgical procedure should be planned so that the patient, with the least possible risk and loss of time, will receive the greatest possible benefit. To-day industry is on a full-time basis, and every unnecessary day that the patient is disabled is an economic loss. To perform several operations when one would suffice, and thus deduce an apparatus but not a true reduction in mortality, to use a type of incision not strictly indicated for the work at hand, or to use unnecessary drainage which will confine the patient to bed longer, or leave him with a greater hernia liability, is unjust. This economic loss is illustrated by a comparison, at ten-year intervals, of the hospital morbidity following operations on the biliary tract. The methods in use to-day, as compared with methods used ten years ago, save for each patient operated on in the clinic ten days of hospital time, or thirty-six years of the lifetime of one person each year. The incision used in the majority of operations on the biliary passages has been the incision introduced by Deaver in 1898, slightly modified. The method of Alexander, leaving undivided the posterior aponeurosis, the peritoneum, and the nerves in the lower third of the incision, is followed because the posterior aponeurosis, peritoneum, and nerves are sufficiently mobile to be drawn down readily by a retractor.

of stones, especially if the gall bladder has been removed at the first operation, may be most difficult, particularly if dense adhesions bind the area in a confused mat, and a state of hepatitis, or biliary cirrhosis, makes the liver bleed at a touch.

The importance of removing all stones from the common duct cannot be overestimated. In nearly one-third of the deaths following operation on the common duct for stone in our series, *post-mortem* examination revealed that all stones had not been removed. Since *post-mortem* examinations are made on more than 90 per cent. of patients who die in the hospital, this checking up has been of very great importance in adding to knowledge, although often most humiliating to the surgeon. Perhaps some of the stones which are supposed to have re-formed in the common duct are left-overs.

Next to gall stones in the hepatic and common ducts, operative injuries during cholecystectomy are the most common cause for operations on the common duct. The most serious and difficult operations are those which have for their purpose restoration of totally interrupted biliary connexion between the liver and the intestinal tract. When the common or hepatic duct has been injured, and the fact has been recognized at the time, failure successfully to repair the injured duct has not occurred in a single instance. A study of the operative methods employed in these cases, from the standpoint of ultimate results, indicates that in any case in which a piece of the duct has been accidentally removed, and the injury not discovered and repaired at the time, thus necessitating secondary reconstruction, direct union between the stump of the hepatic duct and the duodenum is the best operation.

Of the causes of death after operation, haemorrhage, hepatic and renal insufficiency, and infections of the bile ducts are the most common. These conditions are directly related to the existing chronic obstructive jaundice, hepatitis, biliary cirrhosis, dehydration, and chronic under-nourishment. Walters reviewed the *post-mortem* records, for a five-year period, of patients who died following operation on the biliary tract, and demonstrated that in 58 per cent. of the patients with jaundice who died within the first week after operation, there was more or less blood in the abdominal cavity, usually the result of oozing from slight injuries to the liver. Of itself the haemorrhage was not always sufficient to cause death, but it was a contributing factor. In jaundiced patients in poor condition, unless there is a definite indication, cholecystectomy is not added to the risk of operation on the common bile duct because of the danger of injury to the liver, which adds to the possibility of slow post-operative oozing.

As these patients are dehydrated and usually unable to take much nourishment, an attempt is made before operation to introduce a quantity of water into the system to aid renal elimination. As a rule it is difficult to accomplish this by mouth; it is best accomplished by proctoclysis, or subcutaneously.

A third factor of importance in these cases is hepatic insufficiency, which runs parallel with renal insufficiency. In the presence of hepatic insufficiency the blood sugar may appear to be at the normal level when it is not truly so, because of the concentrated state of the blood from dehydration. Therefore, in the presence of hepatic insufficiency, 5 per cent. glucose, in plain water by rectum, or 3 per cent. in sodium chloride solution subcutaneously, is given.

In order to check the haemorrhage calcium chloride intravenously has proved effective, and in certain cases blood transfusion is a remedy of remarkable efficiency. Failure of normal blood-clotting in the jaundiced patient is a specific indication of deprivation of blood calcium. It remained for Lee and Vincent to give calcium in a 10 per cent. aqueous solution intravenously, with striking results. When the administration of calcium fails to reduce the clotting time to normal, blood transfusion will usually cause a temporary reduction in the clotting time sufficient for an operation to be performed.

The careful pre-operative management of jaundiced patients has greatly reduced the mortality of operations. In two years in not a single instance in the clinic has a patient so prepared died from haemorrhage following the operation.

## CASES ILLUSTRATING METHODS OF DIAGNOSIS IN RENAL SURGERY.\*

(With Special Plate.)

BY

F. STRONG HEANEY, M.A., M.D., F.R.C.S. (IRE.),  
HONORARY SURGEON, LIVERPOOL STANLEY HOSPITAL AND LIVERPOOL  
CANCER HOSPITAL; LECTURER IN CLINICAL SURGERY IN  
LIVERPOOL UNIVERSITY.

In spite of its already voluminous literature, the subject of cystoscopy, pyelography, and ureterography is so important that no apology is needed for bringing forward some interesting points in the application of these methods of diagnosis.

Kidney or ureter cases usually present themselves for investigation because of one or other of the symptoms—pain, haematuria, dysuria, or pyuria which does not yield to potassium citrate or the usual urinary antiseptics. On the other hand, some cases which eventually prove to be of urinary origin come under observation because of symptoms not necessarily suggesting the upper urinary tract as the seat of trouble; for example, in one case which I shall quote, asthma was the only symptom of ill health in the first instance.

Assuming that one of the typical urinary symptoms is present, that a pathological and bacteriological examination of the urine, and a clinical and x-ray examination of the renal, ureteric, and bladder regions have been made, an approximate diagnosis will probably have been reached, but many points will still remain to be investigated. Thus, if pyuria is present, the question whether it is of bladder or renal origin remains. The general recognition of the fact that most cases of persistent pyuria are of renal origin must be credited to the wide adoption of cystoscopy. Simple observation of the ureteric orifices or ureteral catheterization will localize infection or haemorrhage to one or other kidney. The ureteric catheter will provide material for estimating the efficiency of each kidney. Catheterization and aspiration may determine the existence of a hydro-nephrosis.

In almost every case pyelography will contribute some fresh details in the investigation. In renal calculus one will learn whether the stone is in the renal pelvis or in a calyx—an important point in planning operation. The shadow of a ureteral stone can be differentiated from other shadows like it by a pyelogram, but sometimes an x-ray photograph of the opaque ureteral bougie *in situ* will suffice. The cases mentioned below will illustrate these among other points.

The method of performing cystoscopy and of obtaining a pyelogram are now standardized. In injecting the ureters one depends on the patient's sensation of fullness or pain to indicate when enough of the opaque solution has been injected. For ordinary cases no special apparatus is necessary, save the cystoscope, ureteral catheters, and access to a radiologist. Dr. Oram has taken all the photographs in the cases mentioned in this paper. In most cases the ordinary x-ray couch serves for the various cystoscopic procedures, and conversely the x-ray tube can be used with the patient resting on the cystoscopy table. The latter arrangement will suit best when a photograph in semi-upright position is desired.

*The first case I shall mention is one illustrating how, in certain cases of chronic pyuria, cystoscopy by itself excludes the bladder, and localizes the active septic focus to the kidney.*

### CASE I.

Some six months before I saw him, the patient, a man of 53, had an acute attack of cystitis with frequent micturition, suprapubic pain, and abundant pus in the urine. The attack came on after six hours' exposure to tropical rain. He was very ill and was admitted to a foreign hospital, where his bladder was washed out several times a day and urinary antiseptics administered. Under treatment his symptoms improved, but albumin and pus, as well as staphylococci and a coliform bacillus, remained constantly in the urine. On examination one saw that the mucous membrane was healthy everywhere save at the orifice of the right ureter,

\* A paper read at a clinical meeting of the Lancashire and Cheshire Branch of the British Medical Association.

twenty-five years previously she had had haematuria, and increased frequency of micturition, lasting over a period of six months. With all this a laboratory fact it was possible to realize what had occurred. At the age of 15 to 17 she had suffered from an active tuberculous kidney. The caseous debris had, later, blocked the left ureter and allowed the secondary ulceration of the bladder to heal. In this case I removed the kidney, or rather its representative—a large sac of caseous matter contained in the fatty capsule, subdivided by fibrous strands, but containing no trace of kidney tissue (Fig. A). Probably there had been no trace of secreting tissue for over twenty years.

The differentiation of the x-ray shadow of a phlebitis of a mesenteric gland from that of ureteral stone is frequently necessary. I will first show the appearance of genuine ureteral calculus in relation to the opaque bougie and the opaque injection, and then show cases where the phlegmon or ureteroinjection excludes the possibility of urinary calculus in favour of phlebitis or calcareous gland.

In contrast with the case just mentioned is that of a medical student, aged 20, who had suffered from pains in the right iliac fossa and inguinal region for some months. The pains had recently disappeared, but while they were present, he had occasionally been accompanied by haematuria. A small calculus, which Dr. Duffield analysed and further examined by bacteriological methods, was removed from the right ureter. A radiogram showed a shadow of the brim of the pelvis over the course of the ureter, and by question arose as to whether this shadow was a calculus or a calcareous gland. Calcareization of the ureter could only be effected to the extent of a couple of inches (Fig. 5), but on inspecting the ureter with sodium bromide the shadow, though in contact with that of the ureter, was seen to be independent of the latter (Fig. 6). The shadow is seen to pass the region of the doubtful shadow without dilatation or distortion—in contrast to the shadow seen in the previous case, where the injecting solution is seen to surround the stone. The shadow in the present case is evidently that of a mesenteric gland.

left ureter. In the absence of pus or x-ray evidence of stone, the presumption was in favour of a growth of the left kidney. No operation was performed owing to the feeble condition of the patient, but the rapid increase in size of a gland above the left clavicle confirmed the existence of malignant disease in the drainage area of the thoracic duct. The shadows in the pelvis were phleboliths.

## CASE VII.

This patient was a seaman aged 36. When homeward bound from Australia he was seized with severe pain in the right iliac fossa and right testicle. He was obliged to lie up for three or four days. He was then transferred to hospital ashore at a Mediterranean port. There he was x-rayed and a diagnosis of calculi in the pelvic ureter on the right side was made. Being anxious to get home he declined treatment and continued his voyage. The severe pain had passed off in two days from its onset, but he suffered from slight abdominal aching for upwards of a fortnight. On reaching Liverpool, two months later, he was referred to me for further investigation and treatment. The urine was normal. Palpation revealed slight tenderness in the right iliac fossa. Radiographically a number of circular shadows were visible in the right lower pelvis (Fig. 9), but a photograph with the opaque bougie in position showed that the shadows lay clear of the ureter (Fig. 10). The renal pelvis was normal.

The original illness was evidently due to appendicitis, of which testicular pain is an occasional symptom. This diagnosis I verified by operation, finding a retrocaecal appendix lying over the course of the ureter, buried in adhesions and acutely kinked.

*A ureteral calculus may exist side by side with a phlebolith, and the latter with its associated fibrosis may prevent the passage downward of the former.*

## CASE VIII.

The patient, a man of 37, suffered from repeated attacks of right loin pain radiating downward to the testicle. A radiogram showed two shadows in the region of the lower right ureter (Fig. 11). The ureteric bougie passed the lower shadow and thrust the upper shadow upwards for a couple of inches before being stopped (Fig. 12). The ureterogram (Fig. 13) showed that the lower shadow lay outside the ureter, and that the injection could not pass backward below the point of the ureter in contact with the phlebolith. The ureteric catheter occupied the entire lumen of the ureter at this point. At operation I found the ureteral calculus lying beside the phlebolith, separated only by the ureteral wall. The phlebolith was surrounded by a mass of fibrous tissue which involved the ureter, and determined the obstruction. The calculus was removed and the obstruction dilated.

*The fact that a pyelogram is normal helps one to exclude the possibility of a surgical condition of the kidney in a doubtful case of loin or abdominal pain.*

## CASE IX.

A woman of 54 complained of a constant aching in the right iliac region. The routine x-ray examination of the urinary tract showed no abnormality. The urine was normal. A pyelogram in the semi-upright position showed a normal renal pelvis (Fig. 14).

The patient is now wearing a visceroprotect belt and has obtained relief.

## CASE X.

A young woman complained of severe pain the left iliac fossa and on the front of the thigh. An x-ray examination of the urinary tract was negative. The urine was normal. A pyelogram taken as in the last case was normal. The pain was so severe that I explored the abdomen, and found high up at the root of the mesentery a large tuberculous gland. Its removal relieved the symptoms. The pyelogram helped to exclude a renal condition, and limited the exploratory operation to the abdominal cavity.

*When an intramural ureteric stone remains in situ for some time the ureteric muscle tires in its efforts to expel it. It is of interest to observe the later changes in the appearances presented at the ureteric orifice.*

## CASE XI.

Shortly after her confinement, a woman came complaining of severe pain in the right inguinal region, coming on at short intervals. There was pyuria and slight haematuria. A rays showed a stone in the lower part of the right ureter (Fig. 15).

Cytoscopically the left ureteric orifice was of the normal slit-like type; the right was a circular dark hole, and any attempt

to pass the urethral bougie brought one up against the stone. When the orifice was kept in view for a short time, one could see the lower pole of the stone rhythmically presenting at the orifice as the ureteric muscle endeavoured to thrust it through. With each contraction one could see round the presenting stone a circle of jets as the urine was forced out. The presentation of the stone in the orifice was sometimes accompanied by distinct pain, and the whole phenomenon was, in miniature, what is seen during a labour pain when the foetal head is presenting and receding. When I first saw her a few months ago she had just been confined and was nursing her baby. As the pain was not severe, and the stone likely to pass spontaneously, I thought it desirable to postpone operation. In the course of five months the stone failed to pass into the bladder, and I have since removed it through the bladder. In the meantime the cystoscopic appearances had altered completely. The stone no longer presented intermittently at the ureteric orifice, and though the kidney still functioned, the efflux trickled away constantly, and not with a periodic jet. The ureter had evidently become dilated and lost its power of rhythmic ejaculation.

*In hydronephrosis it is not always possible to demonstrate the condition by aspiration. The aspirating catheter may not pass the obstruction, and when the syringe is applied nothing may be drawn off. In such a case an opaque injection may be made to pass the obstructing stricture or kink, and the ureterogram or pyelogram to demonstrate the obstruction.*

## CASE XII.

Mrs. D., aged 54, had for six years been suffering from severe spasmodic asthma. She had had various forms of treatment, including Tucker's asthma cure, morphine injections, and adrenaline injections. The adrenaline had the power of cutting short an attack, but there was no means of preventing it. Her doctor found pus in the urine, and with the aid of x rays demonstrated the presence of a large stone in the left kidney (Fig. 16), and some minute shadows in the right (Fig. 17).

As a preliminary to operation I passed the ureteric catheters for differential examination of the urine. On the left side the ureteric catheter passed up to the renal pelvis, and a pyelogram

showed the stone to be situated in a calyx (Fig. 18). In the case of the right side the ureteric catheter failed to advance higher than about 2½ inches from its lower end (Fig. 17), but using a catheter with a terminal opening only, the obstruction proved to be permeable to injection.

The pyelogram (Fig. 19) showed a hydronephrosis and enlargement of the upper ureter; the ureterogram (Fig. 20) showed narrowing of the shadow where the instrument had been stopped. At operation this narrowing was found to be a stricture, not a kink.

Treatment consisted in relieving the stricture in the right ureter and removing the stone from the left kidney. Apart from showing the superiority of the injection over the opaque bougie in certain cases it was of interest to find that the patient was cured of her asthma.

*In contrast with the picture of general dilatation of the upper urinary tract seen in the last case, is the pyelogram of a hydronephrosis caused by obstruction at the uretero-pelvic junction.*

## CASE XIII.

A man of 58 presented typical symptoms of right renal obstruction—pain in the right loin, intermittent haematuria, alkaline urine containing pus. The x-ray photograph showed

faint shadows in the right renal region (Fig. 21). A pyelogram showed dilatation confined to the renal pelvis (Fig. 22), and localized the shadows in the dilated pelvis. At operation an artery was found passing from the aorta to the inner aspect of the kidney, half an inch below the renal sinus. With the kidney *in situ*, the ureter lay in front, and the dilated pelvis behind the vessel. The vessel was removed, also half a dozen stones from the renal pelvis by pyelotomy. The stones were probably secondary to the stasis caused by the abnormal vessel. The shadows seen in Fig. 21 were smaller than the stones themselves. This is explained by the radiogram of the calculi taken after removal (Fig. C). Each stone shows a dense core, and less dense periphery. The core consisted of calcium oxalate, magnesium salts, and albuminous material; the periphery of uric acid and magnesium salts.

Under magnification the original of Fig. C showed the lamination of the periphery of the shadows. In such a case a pyelogram is necessary as a means of fixing the level of the obstruction, and of locating the calculi in the pelvis.

FIG. C.—Case XIII. Stones x-rayed after removal, showing oxalate cores and uric acid and magnesium salts in periphery.

## Observations

ON

FIFTY CASES OF CARCINOMA OF THE CERVIX  
TREATED WITH RADIUM.

BY

MALCOLM DONALDSON, F.R.C.S.ENG.,

ASSISTANT PHYSICIAN ACCOUCHEUR, ST. BARTHOLOMEW'S HOSPITAL;

AND

R. G. CANTI, M.D.CANTAB.,

LECTURER IN BACTERIOLOGY AND BACTERIOLOGIST TO ST. BARTHOLOMEW'S  
HOSPITAL.

## NATURE OF THE RESEARCH.

In June, 1921, the Medical Research Council offered to lend St. Bartholomew's Hospital 324 mg. of radium bromide, to be used solely for the purpose of research.

The hospital authorities gladly accepted this offer, and formed a Radium Committee, which decided that one of the investigations to be carried out should be "the study over a prolonged period of the clinical and pathological changes produced by the action of radium, applied locally, in cases of carcinoma of the cervix." The object of the present paper is to record the results of the work done in this connexion during the last eighteen months.

In carrying out this research, both as regards clinical and histological observations, it was decided not to attempt more than to record the changes produced in the local condition and in the chief clinical symptoms, together with those histological changes which were easily recognizable and lent themselves to more precise classification.

## Irradiation of Cervix.

**Radium.**—The radium available consists of the following:

(1) Two platinum tubes with walls 0.5 mm. thick containing respectively 53.1 and 54.2 mg. radium element. The outside dimensions of the tubes are 4 mm. in diameter and 34.8 mm. in length.

(2) Thirteen platinum needles with walls 0.4 mm. thick, each containing on the average 5.1 mg. radium element. The average outside dimensions of the needles are 1.8 mm. in diameter and 23.5 mm. in length.

(N.P.L. measurements corrected for platinum containers.)

The two tubes, filtered with aluminium, are placed end to end in the cervical canal, and the thirteen needles inserted into the cervical tissue at some distance from the canal and in a circle round it. On a few occasions, the needles before insertion were dipped into sterile Indian ink and allowed to dry. This procedure serves to leave a mark along the track of the needle.

**Dosage.**—The cases are divided into two series. In the first the quantity of radium element varied between 133.3 and 173.6 mg. radium element, the duration of exposure being eight hours. In the second, with one exception, the amount of radium element was 173.6 mg. and the duration of exposure was twenty-four hours.

**Filters.**—The filters employed in the case of the tubes consisted on most occasions of (1) a platinum container, which is 0.5 mm. thick; (2) a covering of aluminium; in the case of the needles, on all occasions the platinum container, 0.4 mm., was the only filter.

**Sterilization of Radium and Filters.**—This was carried out by boiling, the use of soda being avoided.

## Irradiation of the Iliac Glands.

To this end the technique of Daels (of Ghent) was employed. For details of this operation, see a short paper written by one of us (M. D., *Proceedings of the Royal Society of Medicine*, 1922, pp. 67-70.)

## HISTOLOGICAL INVESTIGATIONS.

**Method.**—In undertaking the histological investigations it was considered essential to examine sections of the growth before irradiation and as often after irradiation as circumstances would permit, so that comparative observations could be made from time to time. Owing to the anatomical situation of the lesions there was no difficulty in obtaining at frequent intervals fair-sized portions of the material for examination in the form of "snippings." Further, we

were able to obtain from some of these cases the whole uterus, appendages, and glands by operation, or, as in two cases, at autopsy.

**Technique.**—Formalin was employed for fixation in the earlier cases, but later Zenker's fluid was substituted. Efforts were directed to placing the material in the fixative as soon after it had left the body as possible, and to cut it up into as thin slices as could conveniently be made. Sections were embedded and cut in paraffin, the usual technique being employed. As a routine staining, haematoxylin and eosin were used, but where special nuclear detail was required, the sections were stained with iron haematoxylin.

## Results of Histological Examination.

In order that we might arrive at conclusions with the least possible bias, we made a careful analysis of our protocol, which was compiled without preconceived ideas as the sections came to hand.

## I. Eight-Hour Series.

The observations in this series were made on cases examined at different times from one to sixty-two weeks after first irradiation (see chart); the majority of cases having more than one such application, and the dose varying between 133.3 and 173.6 mg. of radium element. The series comprises 14 cases of squamous-celled carcinoma. Of this number, 9 were examined both before and after treatment and are included in the chart. Growth was present in 8 after irradiation, and in the remaining case of the 9 (No. 8) a few cells of doubtful nature were found. Of the 5 not included in the chart, 2 were not examined before irradiation, and 3 did not present themselves for examination after treatment.

The material after treatment was obtained by hysterectomy in three (Nos. 5, 13, and 15) and at autopsy in two (Nos. 1 and 6), and by snippings in the remainder. Seven out of the nine received one irradiation before the second observation, and two (Nos. 2 and 8) received two irradiations, one of the latter being the case in which the only possible evidence of carcinoma was a few cells of doubtful nature.

## Characters of Growth and Surrounding Tissues.

Certain of the main characters of the growth are mentioned here for comparison with the twenty-four-hour series, and will be found in more detail under that heading.

**Cell Division.**—In this series, 5 cases showed mitosis after irradiation; in 2 of these mitosis appeared more abundant than before; in 2 other cases mitosis had apparently disappeared after irradiation.

**Large Nuclei.**—These were seen in 3 cases, in one of which they were present before irradiation.

**Small Round-celled Infiltration.**—This was always found at the spreading edge of growth before and after irradiation, except in one case (No. 15) where it was absent after treatment.

**Fibrosis.**—This is not a marked characteristic in this series.

**Encapsulation of new growth** was not found in this series.

## II. Twenty-four-Hour Series.

The observations were made on cases examined at different times up to forty-nine weeks after irradiation. The full quantity of radium was given on almost every occasion, the number of applications being two or more in the majority of cases (see chart). The series consists of 34 cases of squamous-celled carcinoma and 2 of columnar-celled carcinoma (Nos. 47 and 54), in which sections were taken both before and after irradiation. In addition, there were 2 cases in which no sections were taken before irradiation; and in 3 cases no sections were taken after irradiation, and thus are of no histological value.

In the 34 cases of squamous-celled carcinoma we were unable to find any growth after treatment in 22, and found growth in all stages of degeneration in the remaining 12. Two of these latter, however, contained bodies, for the most part structureless, but which appear to be the remains of new growth cells.

## Twenty-two Cases in which no New Growth was found in the Cervix after Treatment.

From these the material was obtained by hysterectomy in 7 (Nos. 26, 27, 34, 36, 37, 45, 57), sections being cut at different levels. Four of these 7 cases were irradiated twice before the hysterectomy was performed, and 5 were treated once only before operation. In the remaining 15 cases, the material was obtained by "snippings"—in 14 cases after one irradiation, in one case after two irradiations.

## Twelve Cases in which Growth was present in the Cervix after Treatment.

Growth was found to be present in 12 cases, but, as will

be seen later, the amount of growth was considerably reduced. Further, the general microscopic appearances of the growth differed markedly from that of the original, and in some cases it was barely recognizable as such (Cases 22, 23, 33). All these 12 cases, with 5 exceptions, received one irradiation. Of the 3 exceptions, one (No. 24) received two doses before the second observation was made, the other 2 cases (Nos. 35 and 48) received one dose before the second and third observations respectively. Of these 12 cases, the material was obtained by hysterectomy in 4 and by "snippings" in 8.

**Characters of Growth and Surrounding Tissues.**  
After irradiation, cases have been observed on the first day (that is, at the time of removal of radium), also on the second, fourth, and seventh days, and henceforward at varying intervals up to forty-nine weeks.

In the sections taken on the days immediately following irradiation considerable changes were noted. In some cases these were more marked than in others, probably owing to the proximity of the source of irradiation. In a section taken immediately after removal of radium the appearances were not dissimilar to those in the section taken before treatment—namely, normal mitotic figures were present in small numbers, and degenerate mitoses were occasionally seen. In a section taken on the third day, mitotic figures were much more numerous, normal prophase and metaphase were frequently seen, together with undoubted mitoses showing an irregular arrangement of chromosomes and occasionally multipolar-spindle figures. These changes were still more marked on the fourth day, when there was hardly a cell without abnormalities of one kind or

N.B.—Some cases are omitted from the above series because the patient refused further examination, and a few because no section was obtained before treatment. Explanation of Signs.—0 = No change found. (X) = Slight changes found. P = Section obtained post mortem. H = Section obtained from hysterectomy. S = Section obtained from snipping. The small figures 1 and 2 denote date of second and third doses respectively. For amount of radium used see text.

another. These abnormalities consisted of (a) Abnormal mitosis, (b) Necrosis, (c) Increase in size of the cell. Almost 50 per cent. of the cells showed absence of nuclear boundary and of these a large number showed degenerative mitoses. Prophase was occasionally seen, metaphase was abundant, but the later stages of division were not observed. Cells showing granular and fragmented chromosomes were seen in large numbers. Some of them showed well formed spindle figures, but others showed only occasional scattered threads, the nature of which was doubtful, and we were unable to decide whether these latter cells were undergoing mitosis or were in a process of dissolution, especially as the cytoplasm of some of them was broken into droplets. In other cells, the chromosomes had almost entirely disappeared, the spindle figure alone being seen.

(b) Necrosis.—In some areas the tissue as a whole had undergone complete loss of power to take up nuclear stain, while the general structure of the tissue was maintained. These areas, we believe, were in close proximity to the radium.

(c) Increase in Size.—The remainder of the new growth cells showed some increase in size compared with those in the original growth, and further, their nuclei were enlarged.

**Later Changes.**  
From the seventh day onwards no mitoses of any kind were observed, an observation which would seem to be of considerable importance. The nuclei appeared to be broken up, the chromatin being distributed in the cytoplasm as droplets or irregular particles; irregular staining was no longer frequent, but when it did occur the nuclei frequently assumed irregular and angular outlines, staining indifferently and unevenly, their appearance being more like that of an inorganic than of a biological substance.

In certain cases observed at a still later date the nucleus was no longer distinguishable, but masses of unorganized material, often concentrically laminated, were seen. These masses usually take up haematoxylin to a moderate extent. They are stained deep blue by a well matured Nile blue solution and red with murexcarmine, especially with regard to their outer laminations.

Large nuclei were observed in 3 cases and were usually accompanied by a great increase in the amount of cytoplasm. They were deeply staining and had irregular and often "blurred" outlines. Although such nuclei are occasionally observed in untreated growths, and were undoubtedly seen in one of these cases, yet there is no question that they occur much more frequently after irradiation.

Small round-celled infiltration to a greater or less amount was always found before irradiation at the spreading edge of the growth or between the finger-like processes. In sections taken nine weeks after treatment it was still found, but later than this was no longer present. It is remarkable that the absence of small round-celled infiltration seems to correspond with the presence of the later type of nuclear change mentioned above.

Polymorphonuclear cells were usually found in a breaking down core of a growth, whether it had been irradiated or not. They were seldom seen at the spreading edge of the growth, except in relationship to an ulcerated surface. Occasionally polymorphonuclear cells were seen included in a new growth cell before irradiation, but on three occasions, varying from three to five weeks after treatment, this intracellular invasion was a prominent feature.

Fibrosis was found to be increased in all cases after treatment, especially near the position previously occupied by the radium, as shown by the Indian ink preparations. In the early stages there is a greater number of fibrous tissue cells between the muscle fibres independently of the proximity of new growth. As time continues muscle strands are less frequently met with and may be seen separated by masses of fibrous tissue fibrils. In the later stages no muscle at all, nor nuclei of any cells, are seen, but the micro-anatomical structure of the uterus and its vessels—the latter being by this time thrombosed—is to be seen formed of a quantity of dense fibrous tissue in which relatively few elastic tissue strands are incorporated.

*Encapsulation.*—There was little or no attempt at the formation of fibrous capsules round the growth before irradiation. This was also the rule after irradiation in those cases observed before the eighth week; but in five cases observed on six occasions—at the eighth, ninth, tenth, fifteenth, and forty-ninth weeks respectively—there was a definite sheath of fibrous tissue encircling the growth islets. It is not clear whether this formation is a purposeful reaction on the part of the tissues or whether it is simply a mechanical arrangement of the fibres. It is to be noted that this period corresponds with the later type of nuclear change, and with the absence of small round cells.

#### *Columnar-celled Carcinoma.*

Columnar-celled carcinoma was found in two cases of the 24-hour series. These were irradiated on one occasion only before hysterectomy. Growth was found in these two cases five weeks and nine weeks respectively after irradiation. In both cases the amount was much reduced, and in the second case to such an extent that it was only found in small isolated islets after several sections had been searched. The changes were of a similar nature to those found in the squamous-celled carcinoma.

#### ANALYSIS OF CLINICAL RESULTS.

A concise presentation of the clinical aspects of the cases seems to the authors to be a matter of some difficulty, for while a complete clinical note of each case might be of great value to those who are directly interested in irradiation, yet this is so cumbersome that it was considered that an analysis would be more acceptable to the majority of readers.

The analysis is based upon the effect of irradiation on the four cardinal signs and symptoms—that is, haemorrhage, discharge, ulceration, and induration—and also upon the effect on the length of life and general comfort of the patient, so far as can be estimated at the present juncture.

As the immediate object in view is to show the effect of irradiation on the cervix, those cases in which hysterectomies have been performed are necessarily omitted from this analysis, but are included in the histological investigations.

#### *Analysis of 8-hour Series.*

Reviewing first the 8-hour series, we find that there were 14 cases treated, and of these 5 had hysterectomies performed, leaving 9 inoperable cases for analysis, but detailed information of subsequent history could not be obtained from 3 of these.

*Length of Life.*—Of these 9 cases, 2 (Nos. 4 and 3) have been treated for twenty and eighteen months respectively, and are still living. One of these cases (No. 4) is extremely well, and able to do her daily work; in her own words, she "has taken on a new lease of life." On vaginal examination it is found that the walls have become densely adherent, making it impossible to see the cervix. Per rectum there is some thickening to the left and to the front of the rectum. It is doubtful whether this is fibrous tissue or new growth. This patient, however, was found to have a fresh nodule of growth in the vagina after fifteen months. This was treated with 66.3 mg. of radium element for 24 hours, and at the same time deep irradiation was done by Daels's method. The second patient (No. 8) was very much improved for fifteen weeks, but is now not doing well, and when last heard of was rapidly going downhill. Of the remaining 7, 1 lived three, 1 sixteen, and 2 nine months respectively; 1 died of septicaemia within a few weeks of the insertion of radium, and 2 were notified as having died about four months after treatment began.

*Haemorrhage.*—Of the 5 cases in which this symptom was noted, haemorrhage ceased entirely after treatment in 4, and in 1 the amount was diminished.

*Vaginal Discharge.*—This cleared up entirely in 1 case, and was diminished in 4.

*Ulceration.*—This cleared up entirely in 2 cases, was diminished in 2, and remained the same in 1.

*Induration.*—It is always difficult to gauge how much of the induration present is growth and how much fibrous tissue caused by infection or as a result of treatment. In no case has the induration entirely cleared up, but in 1 case it was markedly diminished, in 2 somewhat diminished, in 1 somewhat increased, and in 1 remained the same.

*Summary.*—Two cases were decidedly improved, 2 cases slightly improved, in 4 cases there was no alteration, and 1 case died shortly after treatment.

#### *Analysis of 24-hour Series.*

Reviewing now the 24-hour series, one finds that 41 cases were treated, and of these 13 had hysterectomies performed, and 2 of the remaining cases have been treated so recently (within three months) as to be of no value in discussing results. This leaves 26 inoperable cases for analysis in detail.

Of these 26, 10 have died, 1 could not be traced, 15 are still living after periods varying from four to sixteen months, and in 7 of these treatment was commenced more than twelve months ago. Of these 15, 4 are deserving of special remark. One (No. 49) was treated with deep x rays by Dr. Finzi after one application of radium. Another (No. 23) is extremely interesting. After one application, she was considered to be too advanced for further treatment. It was, therefore, a very great surprise to find that six months later she had entered another department of the hospital and had undergone an operation for gall stones. Some months after the treatment she developed a vesico-vaginal fistula, the edges of which are at the present time composed of healthy-looking epithelial tissue. She is still alive more than twelve months after treatment and appears to be in good health. One case (No. 21) is still living after sixteen months, and feels extremely well; the local condition shows the vagina walls to be somewhat adherent, but on separating these the cervix is revealed as an atrophied nodule of fibrous tissue. There is some induration in the fornices. Another (No. 17) has been under treatment for thirteen months, is extremely well, and doing her daily work. Of the remaining 11, the majority were markedly improved for a time, but some now seem to be on the downward grade. Of the 10 who died the term of life after treatment varied up to fourteen months. In nearly every case the patient had a considerable amount of growth in the parametria

tissue and glands, which in 2 cases caused intestinal

obstruction.

**Deconvolution.**—This symptom almost invariably yields

to treatment, and we find that it usually ceases within a

week or so of the first irradiation. It ceased entirely in 22

of the 25 cases; in 2 others it was absent for a time but

recurred. In 1 case it was diminished.

**Urinary Discharge.**—In 11 cases discharge disappeared

entirely; in 2 it ceased but recurred, and in 12 it was not

diminished.

**Leucorrhea.**—In 10 cases leucorrhea cleared up entirely;

in 2 it disappeared entirely but recurred; in 6 cases it was

diminished, but never entirely disappeared. No change

took place in 7 cases.

**Induration.**—Induration was markedly diminished for a

time in 1 case. This was the one referred to above, which

was treated by Dr. Kinn by means of deep x rays. Indura-

tion was slightly diminished in 3, markedly increased in 3,

and not altered in 17. In 1 case it was markedly diminished

for a time but increased later.

**Summary.**—Of the 25 cases traced, 13 are still living,

and 3 remain well after more than a year. Definite

improvement was made in 13 cases, slight improvement in

10; in 1 treatment seemed to have no beneficial effect what-

ever, and in 1 pain was actually increased.

#### DISCUSSION OF RESULTS.

The present-day knowledge concerning the action of

irradiation and results hitherto published appear to the

writers to be quite inadequate to justify any discussion

as to the relative merits of this form of treatment as com-

pared to operation, and the majority of people in this

country agree that at present radical operations should

be performed for carcinoma of the cervix wherever that

procedure is possible, whether or not irradiation is employed

in addition. Nevertheless, the most optimistic of surgeons

cannot but deplore the small number of cases that can be

said to be cured, considering the prevalence of the disease.

It is therefore essential that we should no longer resign

ourselves to this hopeless state of affairs, but should invest-

igate fully any method which offers hope of bettering the

present conditions. It must be remembered that the treat-

ment by irradiation is, comparatively speaking, in its

infancy, and therefore, in spite of the promising nature of

the results so far obtained, we must not, at present, expect

to effect permanent cures. As has been seen, certain

#### HISTOLOGY.

Before discussing the histological results in detail, it is

necessary to bear in mind certain preliminary con-

siderations.

First, it is usual to find in untreated carcinoma a greater

or smaller number of cells undergoing degenerative changes;

but whilst it might seem that these changes would vitiate

the conclusions arrived at on the effect of the irradiation,

yet a careful comparison of the sections before and after

treatment will leave no doubt that these are due to the

radium.

Secondly, a series of "snippings" in any one case may

differ from one another, because the conditions of sepsis,

blood supply, distance from the situation previously

occupied by radium, and relation of surrounding tissues

are not the same for each successive piece taken. Never-

theless, if all the changes observed trend in the same direc-

tion, it is impossible to believe that they are due to any such

chance causes. Further, in the 8-hour series no striking

differences were observed after treatment, except in one

case, whereas in the 24-hour series a very different state

of affairs exists.

Thirdly, in those cases where growth is absent after treat-

ment it is possible that it may not have been included in

the material obtained. The fact, however, that growth

was always present after treatment in the 8-hour series

(except possibly in one case), and absent in over 60 per

cent of cases in the 24-hour series, makes it extremely

improbable that this can often have occurred.

The quantity of radium in most of the cases has been

kept a constant factor. The time of application has been

respectively, so that the amount of irradiation of the tissues

in the two series is in the proportion of 1 to 3. Marked

differences were obtained in the two sets of cases, and as

are of opinion that irradiation for eight hours is well worth

useless, even if repeated on as many as three occasions;

whereas even one exposure for twenty-four hours has a very

marked effect, and has not infrequently led to the complete

local disappearance of the growth.

Although it is impossible to obtain accurate measure-

ments of the energy at any one point in the pelvis, owing

to the method of distributing the radium, yet it is obvious

of very great intensity compared to that received by the

iliac glands, where the action of the inverse square law

comes into play. Consideration of these facts explains why

no growth can be found in the cervix, but is present and

apparently unaffected in the iliac glands.

The only change after treatment which can be shown

to have any degree of constancy in the 8-hour series is the

appearance of large cells containing large deeply staining

nuclei with irregular outline. This has been seen only in

the first and second weeks after irradiation, and is probably

to be regarded as a degenerative process.

In the 24-hour series the most striking change is the

disappearance of the growth from the cervix in over 60 per

cent of cases of squamous-celled carcinoma. As is to be

expected, this does not take place immediately; the earliest

date on which it was observed was three weeks after irradiation

and this was in a case where the whole uterus was

examined. It is not possible to say how long carcinoma

cells can persist after treatment, but it is interesting to note

that evidence of new growth debris was present in a section

taken forty-nine weeks later. In those cases where new

growth can yet be found, it is present in greatly diminished

amount and shows marked degenerative changes. Con-

sideration of these cases leads us to frame a tentative

hypothesis of the stages through which the cell may proceed

to its doom.

In discussing the sequence of events it is necessary to

bear in mind the physical conditions present in the

irradiated area. The cells closest to the radium receive the

greater amount of energy, and those further away receive

less, both because of the increase in distance and because

a certain amount of energy has already been absorbed.

When a large amount of radium such as we have used is

left in situ for twenty-four hours it seems as if the radia-

tions were sufficient to cause immediate death of all the

cells in close proximity, thus giving rise to the picture of

coagulation necrosis, which in turn disappears within a

few days as the debris is removed. In the zone beyond this

the irradiations do not seem to have an immediate lethal

effect, but about the third day the cells show a breaking

up of the chromatin into droplets accompanied by an

enlargement of the cell itself, and sometimes by a breaking

up of the cytoplasm into a number of small masses. Still

further beyond this zone a large number of cells show

marked activity on the third and fourth days. Mitoses are

much more frequent than in the original growth, but they

are almost entirely of a degenerate nature. They may be

multinuclear or may show granulation and fragmentation of

the chromosomes, or the chromatin may have disappeared

from the cell leaving only the spindle figure. The observa-

tions on which we have based this hypothesis of the stages

in the first four days is in accordance with those published

by A. Lacassagne and O. Monod (*Arch. Trans. Path. Gen.*

*et Exp.*, 1922, Fasc. I, p. 28), but we are not so far in entire

agreement with regard to his interpretation that the pro-

cess of death is degenerative mitosis. When discussing

the matter with J. Laccagny, he pointed out that there

are almost entirely of a degenerate nature. They may be

multinuclear or may show granulation and fragmentation of

the chromosomes, or the chromatin may have disappeared

from the cell leaving only the spindle figure. The observa-

tions on which we have based this hypothesis of the stages

in the first four days is in accordance with those published

by A. Lacassagne and O. Monod (*Arch. Trans. Path. Gen.*

*et Exp.*, 1922, Fasc. I, p. 28), but we are not so far in entire

agreement with regard to his interpretation that the pro-

cess of death is degenerative mitosis. When discussing

the matter with J. Laccagny, he pointed out that there

was a considerable difference in the technique of irradiation employed by him, which fact may account for our interpretation. We are, however, further investigating the changes that occur within the first few days.

From the seventh day onwards there is apparently no attempt at multiplication by mitosis, and we have no evidence that multiplication in any form takes place. The nucleus, on the other hand, assumes strange forms; there is often an increase in size accompanied by an increase in cytoplasm and sometimes very large forms are seen. The outline is irregular and the nucleolus is often deeply stained. Later mottling or even vacuolation (sometimes the vacuoles are of large dimensions) is seen, followed in some places by a gradual loss of staining power whilst the nuclear form is still maintained. The cytoplasm itself is usually increased in quantity, and occasionally shows vacuolation. The tissues around are heavily infiltrated with small round and plasma cells, as before treatment, and in addition there is usually an increase in the amount of fibrous tissue. These appearances last up to six or eight weeks, towards the end of which time the cells, if they have not already disappeared, become difficult to find owing to their paucity. After this stage it seems that the cells entirely vanish from the tissue, except in a few cases where another process seems to be at work, which for want of a better expression we have termed "embalming." Whereas in the former case the cells seem as if they were dissolved and their remains removed, in the present case they appear to remain collected together in their original alveolar forms. The nuclei are sometimes to be recognized by their spherical outline and staining properties, but generally, and especially in the later observations, no nuclear structure is to be seen, and the islets consist of an unorganized mass, often concentrically laminated. These can only be regarded as remains of new growth because (1) they are bodies entirely foreign to the normal cervix; (2) they can be traced in a series of cases through the various stages from unquestionable carcinoma. In this embalmed state there is an entire absence of round-celled and plasma-celled infiltration around, suggesting that the growth is no longer capable of causing cell reaction, and is dead. The islets are often embedded in a mass of dense fibrous tissue or may have muscle tissue in close proximity, but usually there is an attempt at fibrous tissue encapsulation round them. From their staining properties these masses appear to be heterogeneous, but there is evidence that their outer portions contain myxomatous material.

Judging from the observations in one case which was examined fifteen and forty-nine weeks after irradiation, it would seem that when once the cells have reached this advanced stage these masses appear to be relatively permanent.

#### CONCLUSIONS.

##### Clinical.

1. These are in accord with the general experience of others in recent years, that in the majority of cases patients suffering from carcinoma of the cervix cease to have haemorrhage, vaginal discharge, and ulceration after treatment with radium. Further, that in some of those cases which are inoperable, life is prolonged and the patients are enabled to lead useful existences. It would be premature at the present juncture to talk of cures.

2. That the preliminary application of radium in those cases which are operable causes the disappearance of fungating growths or ulcers, so that the risk of infection and of implanting new growth from the cervix at the time of incising the vagina wall is markedly diminished.

3. There is no doubt that the application of 173.6 mg. of radium element for twenty-four hours is markedly more efficient in bringing about this result than the same amount applied for eight hours, even when the latter is given on as many as three occasions.

4. That since histological evidence of the efficacy of Daels's method of irradiation of the pelvic glands is impracticable its value is still *sub judice*, as it depends upon clinical evidence.

##### Histological.

1. That the introduction of 173.6 mg. of radium element into the cervical tissue for twenty-four hours is capable

of causing a complete disappearance of the growth from the cervix within a few weeks, whereas the same application for eight hours produces little or no effect in the quantity or appearance of the growth.

2. That definite series of changes in the carcinoma cells can be demonstrated after irradiation, leading up to the destruction of the cell.

3. That little or no effect has been produced in affected iliac glands when the cervix is irradiated.

4. That as changes in the malignant cells take place before the formation of fibrous tissue, the latter is not the causal agent in the disappearance of growth.

5. That the carcinoma cells are more vulnerable than the uterine musculature, but that in the latter local atrophy and fibrosis take place at a later date.

Our thanks are due to the Medical Research Council and the Radium Committee of St. Bartholomew's Hospital for the facilities given us in carrying out this research; to Dr. Williamson and Dr. Barris for allowing us to irradiate some of their cases and to include them in this series; and to many others for their valuable assistance, but especially to Dr. T. S. P. Strangeways for the whole-hearted manner in which he has given us his assistance and advice.

## Memoranda :

### MEDICAL, SURGICAL, OBSTETRICAL.

#### THE TONGUE SYMPTOM IN ABDOMINAL SEPSIS.

I WOULD like to call attention to a symptom which I have been accustomed to seek in all cases of abdominal disease, and which has not once failed me during many years of practice. I refer to a definite smell in the tongue, which I find present in all cases where pus is present in the peritoneal cavity. I do not refer to the smell of the breath but of the tongue itself. I find the smell varies from the distinct smell of pus to an actual faecal odour, sickening to the observer.

I am unable to find any reference to this symptom in books on surgical diagnosis, but have notes on cases extending as far back as twenty-five years in which I have used this symptom and verified its accuracy by operation. We know how rapid is the absorption from the peritoneum, and it appears to me that the tongue gives the first indication of this absorption. Among many cases of which I have notes I mention only three.

*Case 1.*—A female child had pain in the appendix area, and was sent into a nursing home at once. The temperature was not raised. There was slight rigidity of the abdominal walls. No vomiting. I noted that the tongue smelt very offensively. Operation at once. Perforation of adherent appendix, with offensive fluid in peritoneal cavity.

*Case 2.*—Adult, male. History of two days' illness. Pain not severe. Slight rigidity of abdominal walls. Temperature raised. Tongue smelt faecal. Operation at once. Appendix gangrenous; pus and gas in the peritoneum.

*Case 3.*—Seen in consultation. Adult female. History of obscure pain in left side of pelvis. Definite swelling extending upwards for three inches above iliac crest. Per vaginam tense swelling to left of uterus. The tongue very offensive. Gave advice for immediate operation as I was sure that there was pus in the peritoneal cavity. Operation two hours later. On opening the abdomen in the middle line we found a large collection of pus walled off. The pus had originated in the left broad ligament and ruptured into the peritoneal cavity, becoming walled off by adhesions. Over twenty ounces were evacuated. Recovery was uneventful.

I have tried testing this symptom by getting the patient to gargle and wash out the mouth, but in every case the smell of the tongue remained. In most cases I have noted that the tongue was not covered with fur; usually it is dry and beefy-looking.

I would be very interested to know if others have observed this symptom, which I have learned to rely upon with much confidence.

P. CLENNELL FENWICK, C.M.G., M.D., F.R.C.S. Edin.,  
Consulting Surgeon to Christchurch Hospital, New Zealand.

## British Medical Association.

## CLINICAL AND SCIENTIFIC PROCEEDINGS.

## ASSAM BRANCH.

At the annual general meeting of the Assam Branch of the British Medical Association, held at Haflong on January 7th, with Dr. WINGMASTER in the chair, a number of interesting papers were read.\*

## The Health of the European Community in Assam.

The Chairman read a paper by Dr. C. E. FORSYTH, entitled "Notes on conditions affecting the health of the European community in Assam." Dr. Forsyth was of opinion that prior to the engagement of a young assistant for work in Assam tea-gardens, expert medical examination at home was essential. While suffering from the more obvious disabilities had not been engaged to any great extent for tea-garden work, yet it had been different in the case of those affected with, for example, the minor psychoses, and Assam was no place for the treatment or cure of "shell-shock" or similar conditions. Dr. Forsyth considered that tea companies should not, unless in exceptional circumstances, engage married men new to the country as assistants, nor should directors permit marriage until a man had at least completed his first five years, when he should be in a position to decide for himself. Women withstood life in the tropics or sub-tropics much less easily than men, although conditions in Assam could, in a general way, compare favourably with those prevailing in many other parts of the East.

The strain of life for women in Assam fell especially and prejudicially on the nervous system, and continued residence led to nervous irritability, insomnia, and neurasthenia. Infants did well in Assam, and flourished up to about the age of 5 years, and their removal to the hills in the rains was unnecessary. After the age of 7 or 8 the risk of physical deterioration and mental detriment was markedly great, and after that age home was called for. A certain amount of monotonous life in regard to food could scarcely be avoided, and alcohol other than a whisky and soda at sundown, or with the evening meal, was unnecessary and to be avoided. In regard to special measures against particular diseases, one important matter was the use of quinine as a prophylactic against malaria. Dr. Forsyth's opinion was that 5 grains of quinine given daily in all ordinary circumstances was the optimum prophylactic dose.

*Progress of Kala-azar Work in Assam.*  
Lieut.-Colonel T. McCORMACK YOUNG, I.M.S., Director of Public Health, Assam, read a paper on the progress of kala-azar work in the province of Assam in general and in Shibsagar in particular. He said that Assam was for some unknown reason *par excellence* the home of kala-azar, while the errors of bubonic plague were unknown. The older residents of Assam told gruesome stories of the appalling mortality, formerly, and in the eighties and nineties epidemics of kala-azar swept up the Assam valley. For the last twenty years the importance of vigilance with regard to the prevalence of the disease had been urged by the Government health advisers, and as a result a touring staff of sub-assistant surgeons had been maintained to watch its activities during the quiescent period. In 1917-18 there was an extensive re-subdivision, and in 1919-20 there was an extensive re-division of the disease in the endemic areas previously traversed. Provisionally for Assam, treatment by the intravenous injection of tartar emetic had recently been introduced into India by Sir Leonard Rogers; in 1921 nearly 16,000 kala-azar patients were treated by this method, and in 1922 (excluding December, the returns for which had not yet been received) 16,778 patients had received treatment. Lieut.-Colonel McCORMACK YOUNG gave details of outbreaks at Reoiti-Khopbua and Hundupana, and expressed thankfulness for the introduction of intravenous tartar emetic. In what other disease, he asked, a full report has been published in the printed Proceedings of the Branch.

was there a 95 per cent. cure for a disease the mortality of which was otherwise 80 per cent.? During the present year the total of patients treated would be, he said, nearly 20,000, and Assam within the last two years owed to modern medicine and the Government organization which had placed that treatment within reach at least some 23,000 lives.

## The Calcutta School of Tropical Medicine.

Major R. K. KNOWLES, I.M.S., Professor of Protozoology in the Calcutta School of Tropical Medicine, gave a lantern lecture on the school and its programme of research. Major Knowles detailed the early history of the school and its struggle for existence, and said that it represented and would ever constitute the best memorial to the genius and the determined obstinacy of Sir Leonard Rogers. The completed scheme incorporated four separate but mutually dependent institutions, functioning under a single director as head: the School of Tropical Medicine proper, the object of which was post-graduate teaching and research work; the Institute of Hygiene, with which were incorporated of which was post-graduate teaching and research work; the public health laboratories; the six special research laboratories, which were added to the scheme by public subscription and were financed by the Indian Tea, Jute Mills, and Mining Associations, the Indian Research Fund Association, and by public and private subscriptions; and, finally, the Carmichael Hospital for Tropical Diseases, which at present held 88 beds, but which it was hoped to increase to 114 beds. In regard to kala-azar, co-operative work was being carried on by four departments. The most easily applied method of diagnosis was by spleen puncture, and in 465 consecutive cases of fever and enlarged spleen seen at the school, no less than 300 proved to be kala-azar on spleen puncture; much of the so-called malaria of Bengal was really kala-azar. In regard to treatment, the intravenous administration of sodium antimony tartrate was regarded as the sheet anchor; gingerly had been found to be a safe and most important unsolved problem in tropical medicine. He believed that a domestic insect was concerned, and suggested, as those most worth considering, the bed bug, *Cimex*, the flea, and the sandfly, but those were speculations only. Turning to the consideration of malaria, research work was being carried out by Major Knowles in conjunction with Major Chopra. With regard to the clinical symptoms, but it did not prevent rapid and the most rapid and the most immediate effect upon the administration had its uses, but administration by the mouth remained the most important method. The effects of the other alkaloids contained in cinchona bark were being studied, and Major Knowles had already pointed out the value of quinine in quatern and benign tertian malaria, in which it was six to ten times more efficacious than was quinine. The ordinary plain cinchona febrifuge, which consisted of the total alkaloids minus the extracted quinine, was a more effective remedy for malaria in general than was quinine. Much useful work was also being done in the school on the dysenteries, and the treatment of amoebic dysentery had become almost standardized. After the diagnosis had been confirmed the patient was given a six-day course of combined hypodermic and oral emetics; one grain of emetine was given each two or three grains of bismuth emetine iodide in keratin or morning by injection, and, if the patient could tolerate it, salol coated pills, preceded half an hour earlier by 1/6 to 1/8 grain of opium; after the sixth day the patient was taken off all treatment, except perhaps liquid paraffin for any constipation, and if clinically well he was discharged, but for at least once a week for eight weeks his stools were examined for *E. histolytica* or cysts, and, if necessary, the six days' course was repeated. Major Knowles also detailed the Indian dietetic diseases on which research was being done, such as leishmaniasis and epidemic dropsy of Bengal; and the research work was described that was being carried on in ankylostomiasis, leprosy, tropical skin diseases, and indigenous Indian drugs.

## Reports of Societies.

### SURGERY OF THE BILE PASSAGES.

A MEETING of the Section of Surgery of the Royal Society of Medicine was held on June 27th for a discussion on the surgery of the hepatic and common bile ducts. A report of Dr. WILLIAM J. MAYO's opening paper appears at page 7.

Sir BERKELEY MOYNIHAN commenced his speech by paying a graceful tribute to the pre-eminence in the surgery of the bile passages of his friend Dr. William J. Mayo. Secondary, tertiary, or multiple operations upon the biliary system might be made necessary by a variety of causes. Chief amongst these were the nature and condition of the disease, its complications and remote effects, and imperfect primary operations. There were two factors bringing about the formation of stone—infection reaching the bile channels, and an increase in the cholesterol content of the blood. An infection might reach the gall bladder from several directions—from the blood stream, the bile, by the lymphatics, from the common duct, infected in its turn from the duodenum, or by contiguity. But such an infection might not be primary in the organ from which it was immediately derived. A search for infective lesions should therefore involve a scrutiny of the whole body. Failure to do this might mean a recurrence from stones in the gall bladder, the liver, or its ducts. Cholesterol was known to be present in excess in the blood in certain circumstances. In pathological conditions other than cholelithiasis or cholecystitis low or normal values were usually found. In uncomplicated cases of cholelithiasis the cholesterol blood content tended to be high. In 60 per cent. there was hypercholesterolaemia; although in the remaining 40 per cent. the cholesterol content of the blood was normal, in three-quarters of these cases high normal values had been obtained. In all cases of cholelithiasis a marked fall in the cholesterol content of the blood was observed after operation. In some cases re-examination afterwards showed a subsequent rise, sometimes progressive. These people were continuously hypercholesterolaemic; usually, however, after operation the cholesterol content of the blood fell to normal. It was the speaker's practice not to allow the following articles of diet after operation: Yolk of egg, brains, kidneys, sweetbreads, liver, goose and duck, pork and game, fat, stewed and fried meats, cream and cheese, fresh fruit and green vegetables (for three months), butter (only in small amounts if at all).

Recurrence of symptoms after operation might depend on a number of circumstances. Stones might be overlooked or left behind in any part of the extra-hepatic ducts, including the ampulla of Vater. Frequently the common duct was obviously, even grossly, dilated. The question of how best surgically to diagnose a stone in such a duct was one which surgeons answered differently. The enlargement of glands along the duct, the presence of large nodules in the head of the pancreas, might cause one to be almost confident that a stone was present. The speaker emphatically disagreed with the opinion that in such circumstances the duct should be opened and explored. A probe or even a small scoop could miss a calculus of good size, particularly if it were in a little pocket aside from the main channel of the duct. By far the best method of decision was to place the first and second fingers of the left hand through the foramen of Winslow and the thumb in front of it, and to palpate the duct and compress it between finger and thumb. To an expert hand the smallest fragment of stone would be apparent after the duct had been emptied of bile. When a stone concealed in the ampulla of Vater had been overlooked at the primary operation the duodenum should be opened and McBurney's or Kocher's operation performed. When it was not necessary to open the duodenum the dilatation of the lower part of the duct from above was a most useful procedure. It might be effected by the passage of probes of the type suggested by Mayo, or by the passage of a rubber catheter through the duct into the duodenum.

Another imperfection of operation was to provide inadequate drainage for the particles of grit which were sometimes left in the lower intrahepatic ducts or in the hepatic or common duct. He strongly disagreed with the practice of immediate suture of the duct after choledochotomy. In every case of obstruction of the common duct by a calculus there was cholangitis; often there was mud or sand in addition to the larger stones. With a large solitary stone of recent descent from the gall bladder, immediate suture might sometimes safely be performed. He made it a rule to drain the hepatic duct in all cases of multiple stones. For patients who were gravely ill he often used the method of McArthur of passing a catheter down the duct into the duodenum for the purpose of giving liquid nourishment. Narrowing of the common duct was for the time overcome and drainage was effected. He gave through the tube 5 per cent. to 15 per cent. solution of glucose with a little sodium carbonate by the "drip" method, interrupting the steady flow every three or four hours to give a meal of peptonized milk, beaten eggs, etc. As much as ten to twelve pints of fluid might be introduced during the day; the tube remained in for ten days to a fortnight.

Irrigation of the intrahepatic ducts was sometimes necessary in cases in which the ducts contained great quantities of mud. If typhoid organisms were found in the bile the administration of urotropine by the "thump" method was advisable; 30 grains of acid sodium phosphate in one pint of water were taken during the day, and at night a single dose of urotropine, beginning at 30 grains and increasing to 60 grains, was given. At the end of a week a respite of a few days was allowed and alkalis given; the administration of urotropine was again commenced and again interrupted. In cases of primary cholecystectomy failure to divide the cystic duct at the proper place might be responsible for disaster. There were many anatomical variations. The inviolable rule in the surgery of the gall bladder and of the common duct was to "see exactly what you are doing, and until you see, do nothing." If a part of the hepatic or common bile duct was removed it should be immediately repaired. Sir Berkeley Moynihan considered the question of the operation of choice in a case of cholelithiasis with stones in the gall bladder and common duct. He advocated removal of the gall bladder at the time when the common duct was emptied of stones.

An important group of cases was that of involvement of the pancreas with cholelithiasis. Whether the infection reached the pancreas via the lymphatics or the common duct was still undecided. In any case, it was better to remove the gall bladder than to drain it. Cholecystectomy was beginning to displace cholecystenterostomy in the treatment of chronic pancreatitis. Cases sometimes occurred in which an enlarged, hard, oedematous head of the pancreas, by pressing on the common duct and compressing it, caused stagnation of the bile, cholangitis, and typical symptoms of calculous obstruction. In such cases the T-shaped tube of Kehr might be used to drain the hepatic duct intermittently; or better, two catheters might be introduced, one draining the hepatic duct and the other passing downwards into the duodenum and affording a channel for nourishment.

All the operations upon deeply jaundiced patients raised two questions—that of hepatic insufficiency, and of its avoidance, if such be possible, by an adequate preliminary preparation of the patient; and that of post-operative haemorrhage. The symptoms due to the failure of the liver were apt to come quite unexpectedly. The operation had perhaps presented no unusual difficulties, and the patient left the operation theatre in good condition. For a few days all went well; then one of two events attracted serious attention. The amount of bile discharged might suddenly diminish, or almost cease; jaundice deepened slowly; the pulse became slower; the mind was clouded; nourishment was sparsely taken or refused—when it was well taken vomiting began; the amount of urea in the blood steadily augmented, the patient grew rapidly weaker and died after a period of coma. In these cases, as Walters had shown, it was renal failure consecutive to hepatic failure that caused

death. On the picture so well described by Walters and Farham might be seen:

"Clinical picture of hepatic insufficiency. Usually the first two to eight days after operation, the course is unfavorable; biliary drainage and urinary output are normal, fluids are taken well, the pulse and temperature are normal. One of the first signs of the onset of trouble is pallor and thinning of the bile with marked increase in the flow. This is followed by chills and rigors, and the patient begins to grow weaker. The patient loses volume, and the temperature becomes subnormal. Great weakness. Soon respiratory failing, loss of appetite and muscular weakness. Soon respiratory failing, loss of appetite and muscular weakness. The patient becomes weaker and finally dies. The urinary output remains proportional to the fluid intake throughout, and the urine reveals little or no evidence of marked nephritis. Blood urea remains persistently low."—(Surgery, Gyn. and Obst., 1922, xxxv, 605.)

Post-operative hemorrhage was due to the reduced power of coagulation of the blood, and this depended probably upon a lack of calcium salts. The defibrination of these was made good in two ways—by direct transfusion of blood or by the intravenous administration of 5 ccm. of a 10 per cent. solution of calcium chloride on three successive days, as advised by Walters, and by Lee and Vincent. The giving of calcium salts by the mouth even in colloid form had little effect, when it had any, upon the calcium content of the blood. The coagulation time of the blood might be brought down to the normal or to the near neighborhood of the normal by the intravenous administration, and the operation arrived not at the appropriate moment. In all these cases it was necessary to administer as much glucose as possible by the mouth, and by the rectum; and at the operation to take every care to ligature the smallest vessels. It might sometimes be prudent to postpone the removal of the gall bladder because of the slow but unceasing weeping of blood from the denuded surface of the liver which sometimes followed upon cholecystectomy. Secondary operations upon the biliary system were among the most difficult tasks in surgery. To obtain the best results all the highest qualities of the surgeon were called into play: courage, resource, patience, accuracy and rapidity of judgment, fine craftsmanship, and a tranquillity of mind and action that nothing could disturb.

Mr. JAMES STERNBERG'S remarks were based on his personal experience in the operative treatment of 600 patients with gall stones, in 115 of whom the stones were in the common or hepatic ducts. He pointed out that these complications were due to a failure of efficiency in the earlier stages; they were usually entirely unnecessary complications of gall bladder disease. Save in very rare cases stones did not form primarily in the ducts. He did not believe that, in the operative diagnosis of stones in the common duct, palpation was enough. If the surgeon were suspicious of a stone in this position the duct should be opened. In operating for obstructive jaundice a two-stage procedure was recommended. In ordinary cases he advocated removing the stone and the gall bladder. Prognosis depended on the presence and degree of jaundice and infection. Cholecystectomy for stone confined to the gall bladder had a death rate of less than 2 per cent. In the series of common duct cases in the absence of jaundice there was a mortality of 2.5 per cent.; with severe jaundice it was as high as 27 per cent.

Mr. G. GARY TURNER emphasized the need of great care in the performance of cholecystectomy—which had a direct bearing on the surgery of the common duct. The cystic duct such operation the removed gall bladder should be carefully examined, so that if there was any suspicion of the main duct not having been injured the lesion was fresh. Although some damages repaired while the lesion was fresh. Although some such injuries might fortuitously recover with restoration of function, in his experience the tendency was more often toward obliteration or stricture, and he gave notes of four such cases. Surgical literature had latterly been filled with accounts of operations for the restoration or reconstruction of the bile ducts, which was suggestive that these surgical injuries were more frequent than would be the case would.

lead them to suppose. In dealing surgically with the larger bile ducts certain facts had to be borne in mind. (1) The ducts were elastic and not only retracted when divided, but their ends actually contracted, thus favoring obliteration. (2) Except when fixed by inflammation they lay loosely among the tissues, which formed a natural sheath and protection for them. Hemorrhage and extravasated bile tended to be confined or conducted by these natural sheaths, and the former aided in the obliterative process. (3) The mucous membrane of the ducts had great recuperative power, tended to grow out along the duct, and was very helpful in bridging a gap or making up deficiency. (4) Ducts did not atrophy appreciably or become obliterated as a result of inflammation, these were happenings which depended on inflammation. In the light of these considerations it was clear, he believed, that the most important point in the repair of ducts was to secure approximation of the ends, but not necessarily exact apposition. Too many sutures and too much nicety in suturing were very apt to cause narrowing. The suture line should be the widest part of the duct, and in order to secure this it might be necessary slightly to silt up one end of the duct. Any type of vertical incision through the rectus would give a sufficient exposure provided it was carried right up to the epigastric angle. The use of the Robson position had become well established, but the reversed Trendelenburg posture did not seem so well known, though it had proved very helpful. His experience had taught him that when there had been symptoms pointing to an obstruction or infection of the common duct the latter should always be opened. Small stones, soft stones, and debris might very readily be missed if external palpation alone was depended on. He never concluded an operation on the duct without passing a sound, and he preferred the female bladder sound with a diameter of three-sixteenths of an inch, though the duct into the duodenum.

Mr. A. J. WATKINS dealt with that difficult group of cases in which some form of reconstruction of the common bile duct was necessary. First came the case in which injury had been caused by an operation for cholecystectomy. The many variations in the origin and course of the cystic artery and in the length and position of the cystic duct were responsible for many errors. In the older days when it was more common to commence a cholecystectomy at the fundus of the gall bladder, the common bile duct might easily be pulled up in a loop by tension on the cystic duct and a portion completely resected. As the result of inflammatory adhesions, Hartmann's pouch of the gall bladder might be drawn down and firmly attached to the side of the common bile duct, and this again might be a source of error. The only way to avoid these mistakes was to make a very definite rule that in performing cholecystectomy an incision should first be made in the upper part of the gastro-hepatic omentum and that nothing should be divided until all three ducts were exposed. Congenital absence of the cystic duct was fortunately very rare. When a cholecystectomy was done with this condition present a portion of the common duct was necessarily resected. In early pancreatic disease there might be present obstruction to the lower part of the common duct, and this might in time demand some form of reconstruction operation. Advanced cases of chronic pancreatitis and carcinoma of the head of the pancreas might be associated with the presence of white bile in the gall bladder and passages. The danger in these cases lay in the fact that if the gall bladder were aspirated the condition might be thought to be an obstruction of the cystic duct, and the common duct opened to settle the diagnosis. Frequently this resulted in a permanent biliary fistula. Carcinoma of the common duct was rare, as also was scarring and fibrous stenosis at the junction of all three ducts caused by an impacted stone. The operations for relieving these conditions were numerous. Direct suture was theoretically best, but was frequently very difficult. Suture round a tube was often followed by fistula formation. Without a tube leakage was common and anastomosis was likely to occur. Lateral cholecystectomy was not entirely satisfactory. These operations were gradually being superseded by direct or indirect implantation into the duodenum. Direct implantation into the duodenum, where possible, was the operation of choice. The proximal end of the duct was brought down to the duodenum and

anastomosed to a valvular opening in the wall of the viscus. Without a valvular opening, which was sometimes difficult to make, there was danger of infection from the duodenum and a suppurative cholangitis. He strongly advised an operation of indirect implantation in which a new duct was formed out of a flap of duodenum. This method might be used either when the duct was completely divided or for the formation of a new lateral duct when the original passage was simply dilated above an obstruction.

## PEDIATRICS.

### THE BRISTOL MEETING.

A PROVINCIAL meeting of the Children's Section of the Royal Society of Medicine was held at Bristol on June 22nd and 23rd, with Dr. ERIC PRITCHARD in the chair.

During the first afternoon a demonstration of cases was given at the Bristol Royal Hospital for Sick Children, and a large number of interesting cases were exhibited.

Dr. O. C. M. DAVIS showed the following cases:

- (1) A girl, aged 17, with marked cyanosis, clubbing of fingers, easily provoked dyspnoea, and polycythaemia. There was no cardiac enlargement, no abnormal auscultatory phenomena, and "no enlargement of the spleen."
- (2) A boy, aged 9½, with ichthyosis and congenital heart disease. There was a systolic murmur and thrill with maximum intensity at the aortic area, and slow pulse suggesting aortic stenosis.
- (3) A girl, aged 3½, with congenital absence of iris in both eyes.
- (4) Three cases of mongolism—two with malformation of the ears, and the third with congenital heart disease.
- (5) A boy who suffered from encephalitis lethargica three years ago, now showing after-effects of the paralysis agitans type.
- (6) A girl, liable to severe attacks of bronchial asthma after food indiscretions, greatly relieved by benzyl-benzoate.

Dr. R. H. NORGATE showed four cases of congenital syphilis, one of which exhibited mixed gonococcal and syphilitic lesions, and one, a boy aged 10 years, wasted, with irregular fever, a large heart, systolic murmur and thrill all over precordium, and some considerable splenic enlargement. The diagnosis in this case appeared to be one of congenital syphilis and congenital heart disease, with superimposed subacute bacterial endocarditis.

Dr. E. C. WILLIAMS showed three cases:

- (1) A case of consanguinity—the child of a brother and sister—subject to violent tempers, backward, with a bad circulation, malformation of ear, and exhibiting other signs of mental degeneracy.
- (2) A girl, aged 15, with fibroid phthisis.
- (3) A boy, aged 12, with peroneal type of muscular atrophy. Eight years previously the child was alleged to have been knocked down by a tramcar; wasting of the muscles below the knees has since followed. There is now wasting of muscles below the knees, some talipes equinus, and wasting of the small muscles of the thenar eminence of both hands. The reflexes are normal except for loss of Achilles jerks. Sensations and sphincter are normal.

Mr. HUBERT CHITTY showed cases which included the following:

- (1) A case of myositis ossificans affecting the left arm. Sections show true bone invading the fascia and deep layers of skin.
- (2) Congenital dislocation of the shoulder, the loss of power to rotate the arm outwards being dealt with by osteotomy of the humerus.
- (3) A case showing the result of ankylosing a flail-shoulder due to infantile paralysis.
- (4) So-called lato rickets. The osteotomy fracture in this case remained ununited for months, but union occurred after local injections of colloidal magnesium.
- (5) A girl exhibiting numerous malunited fractures and with mal-junction of the skull—namely, "persistence of frontal groove, large thinly closed anterior fontanelle." X rays showed defective calcification. This case was labelled osteitis fibrosa, but the consensus of opinion of those examining the case was that it was one of osteogenesis imperfecta.

Dr. RICHARD CLARKE showed an infant with loose skin at the nape of the neck and swollen hands and feet due to lymphangiectasis; another with many large hairy moles on the body, face, and limbs; and a case of achondroplasia.

Mr. WILFRID ADAMS showed two cases of ectopic testis, inguinal, treated by orchidopexy; a case of ectopic testis, perineal, and a case of absent radius—both with a view to suggestions as to treatment; a case of haemophilic knee; two cases of Erb's palsy and fractured humerus, treated and cured; and a child of 2 years and 4 months with an ovarian dermoid cyst, in which acute torsion had taken place, followed by operation and cure.

Dr. GEORGE HALL showed a child of 3 years with hemi-hypertrophy affecting both bones and soft parts of the whole of the right side of the body.

Mr. L. N. MORRIS showed a case of tuberculous disease of the hip with large abscess and disintegration of head of femur, cured by fixation and repeated aspiration; a case of osteomyelitis of lower end of femur, with secondary streptococcal infection of knee-joint; several cases of deformed feet illustrating end-results of tendon transplantation; and a case of median fistula of the neck.

Owing to the large number of cases exhibited there was no time available for a formal discussion, and the meeting adjourned to the University of Bristol, where three short addresses were given: (1) Acute nasal sinus disease in young children, by Mr. E. Watson-Williams; (2) The Schick reaction and diphtheria anaphylaxis, by Dr. J. A. Nixon; (3) The clinical significance of certain urinary conditions in children, by Dr. O. C. M. Davis.

Mr. E. WATSON-WILLIAMS showed two cases in which he had operated for acute nasal sinus disease, both patients being 3 years of age. The onset was sudden, a week after severe colds, with redness and swelling of the whole cheek, and fever. Teeth, normal.

Case 1.—Right nasal discharge of offensive pus. Antral exploration with suction syringe: Right side pus, culture streptococci; left side clear, culture negative. Right intranasal antral operation. Subsequent daily lavage—cure (shown three and a half months later).

Case 2.—Nasal discharge reported, none seen. Right antrum contained pus, culture streptococci; left antrum clear, but culture streptococci. Right intranasal antral operation. Temporary relief (two months), but relapse has just occurred with bilateral discharge.

In his paper Mr. E. Watson-Williams briefly reviewed the anatomy, frequency, symptoms, diagnosis, treatment, and literature of acute nasal sinus disease in children, and pointed out that one must separate the acute maxillary osteomyelitis of infants, in which the antral infection was a small part of a graver condition, from antral sinusitis resembling that of the adult. Most cases were not seen in the acute stage. Chronic nasal sinus disease in even young children was becoming recognized as by no means rare. Occasionally cases were found with acute symptoms of suppuration. In operating, the small size and high floor of the antrum must be remembered, as also the proximity of the dental germs. From these anatomical considerations exploratory puncture through the middle meatus was preferable to puncture through the inferior meatus.

Dr. J. A. NIXON, in his paper on the Schick reaction and diphtheria anaphylaxis, emphasized some of the drawbacks and difficulties which might arise in the performance of this test. He mentioned the fallacies that might arise from errors of technique and deterioration of test toxin. He discussed the question of interpretation of results, dividing these into frankly positive, frankly negative, and pseudo-positive and pseudo-negative. He pointed out that while as a general rule this test distinguished the susceptible from the immune, yet exceptions did occur in which cases giving a negative reaction developed diphtheria; while certain cases with sufficient antitoxin in the blood gave a positive reaction. He quoted also certain cases that clinically and morphologically had diphtheria but gave a negative reaction, and other cases which showed that immunization would not always protect against massive doses of infection. As an indication of the value of the test and of the immunity that might be acquired from inoculation with toxin-antitoxin, he gave the results of an examination of 201 members of the staff of a hospital which had been suffering from an outbreak of diphtheria. Of these, 77 were positive or pseudo-positive and were immunized with toxin-antitoxin; the remaining 124 were negative, and of these 18 had had diphtheria. After immunization only 4 cases contracted diphtheria, and 2 of these were almost immediately following their immunization. In answer to the President and other members, Dr. Nixon said the test was of no value in children under 5 years of age; that it could not be utilized in the detection of carriers, the identification of whom must still be dependent on careful examination of nose and throat swabs; and finally, that it gave no evidence as to the virulence or avirulence of any infection, the estimation of which must depend still on animal experiment.

Dr. O. C. M. DAVIS read some preliminary notes on a research which he had been carrying out for four years in conjunction with Dr. F. W. RIXON. The remarks made referred to a possible mathematical relationship between urinary acidity and combined ammonia, as determined by Folin's method.

The amount of decinormal alkali required to neutralize 25 c.cm. of urine, using phenolphthalein as indicator, was referred to as Titration I, and the further amount of alkali required to react with the acid liberated from the neutralized urine by a neutral solution of formaldehyde was referred to as Titration II.

"R" =  $\frac{\text{Titration I}}{\text{Titration II}}$ .

Dr. Davis pointed out that there was clinical evidence to show that in certain pathological conditions (quite apart from ketosis) the value of "R" was increased, and he considered that it was to some extent a measure of the physiological activity of the liver of the individual under observation. He thought that there was little doubt that many adults and children when in good health could maintain a fairly constant magnitude for "R," whereas others seemed unable to do so.

## Rebifus.

**NON-SURGICAL DRAINAGE OF THE BILIARY TRACT.** DR. B. B. VINCIGRAT LYON, whose numerous reports on his method of draining the biliary tract by aspiration through a duodenal tube have excited much interest and discussion, has now collected his results into a volume of over 600 pages, entitled *Non-Surgical Drainage of the Gall Tract*. His work on these lines began in April, 1917, and as the first of the series of papers appeared in September, 1919, much investigation was carried out before any conclusions were made public. The starting point of this method was the observation contained in Meitzner's paper in 1917 on the law of contrary innervation that by spraying the biliary papilla with a 25 per cent. solution of magnesium sulphate the tonic contraction of Oddi's sphincter at the lower end of the common bile duct is inhibited so that bile flows into the duodenum. Meitzner's further suggestion that by means of the duodenal tube the solution of magnesium sulphate could be applied and the bile then withdrawn and examined was elaborated and applied in practice by Lyon. In health the first bile thus obtained is of perfectly transparent, of medium viscosity, like syrup, and 30 c.cm. of this "A" bile from the common duct, the bile suddenly deepens to a considerably darker golden yellow colour and becomes more viscid, and is thought to be the contents of the gall bladder. After a flow of 10 to 75 c.cm. of this so-called "B" bile there is a third transition and the bile is of a light lemon colour and is thinner and more limpid than either of the two previous specimens; this kind of bile can be received into separate bottles and examined microscopically, chemically, and bacteriologically so that a diagnosis of disease and of the infecting organisms can be made. Lyon goes further than Meitzner in believing that magnesium sulphate causes contraction of the gall bladder as well as relaxation of Oddi's sphincter; these views have met with considerable criticism from Crohn, Bassler, and others, and Max Kohnen, the inventor of the modern duodenal tube (1909), argues that the changes in the colour of the bile are due to the action of the magnesium sulphate and are not indications of the site from which the bile comes. These objections to the fundamental principles of the method are answered at length by Lyon, whose book is intended to show that non-surgical drainage of the biliary tract is a practical procedure and within certain limits is of use both in the diagnosis and the treatment of some forms of biliary diseases. A full account, copiously illustrated, is given of the technique of medical drainage of the biliary tract, which is elaborated, for special precautions must be taken to

## PUBLIC HEALTH AND ADMINISTRATION.

The codification of the law relating to public health and sanitation is becoming more urgent year by year and it is not for the assistance of certain textbooks in discussing acts of Parliament, departmental orders, regulations, and the like, the difficulties of officials concerned with the biliary tract, for special precautions must be taken to prevent continuation of the tube during its passage; the method is of value in the early diagnosis of biliary infection and of biliary stasis. It is held to have a wide field of usefulness in the treatment not only of mild cholangitis and biliary stasis but also as an alternative method of treatment in many forms of gall-bladder disease in which the question of immediate surgical interference arises, and as a supplementary method of maintaining after operation the surgical principles of drainage in cases incompletely cured by surgical measures alone. As an example of its value in simple catarrhal jaundice it may be mentioned that the duration of the disease was reduced by 52 per cent. as compared with another series treated on ordinary lines. Many illustrative cases are given in full with instructive commentaries. The author must be congratulated on the results of his prolonged and successful work.

**THE PREMATURE INFANT.** In the preface to his work on *Premature and Congenitally Diseased Infants* Dr. Julius H. Hess contends that the number of premature births has increased during recent years, and states that of 2,806 deaths of infants occurring in Chicago during one year, 739 in the first month were due to prematurity. The book is divided into four parts: the first is devoted to etiology, physiology, and pathology; the second to nursing and feeding; the third to general diseases; and the fourth to prognosis. The chapter on physiology in Part I contains useful tables of the body weight and other measurements drawn from various authorities as well as by the author. Emphasis is laid on the value of x-ray examination for determining the age of the foetus, since osseous development is more regular and offers more factors for consideration than the length and other measurements. A diagram of the development of the centres in each bone based on roentgenographic studies of 55 cases. In the chapter on pathology, which is based on the work of Hippo, it is stated that premature birth should be looked on as a traumatic process in which the characteristic lesions are most frequently found in three groups of organs—the skull with the brain and membranes, including the spinal cord, the lungs, and the gastro-intestinal canal. The second part contains chapters on maternal nursing, the selection and hygiene of the wet-nurse, the care and nursing of premature infants, and the methods of feeding. Premature infants are considered in two groups according as they can or cannot be breast-fed. The important rules to be observed in the case of these infants are maintenance of the body-heat from birth, careful individual handling with prevention of infection, and breast milk. Administration of orange juice as an antiscorbutic is commenced at three weeks, and cod-liver oil for its antirachitic properties at four weeks, irrespective of the type of feeding. A special chapter is devoted to incubators, with an account of their history from the time of Denue in 1857 to the present day, illustrated by numerous photographs of various models. The third part deals with general diseases and the fourth with prognosis. The author considers that the future of premature infants who survive is, on the whole, good. Though they are somewhat more subject to hydrocephalus and to psychic and nervous anomalies, as well as to rickets, anæmia, and tetany, by the time that puberty is reached most of the differences between the premature and the full-term child will have disappeared. Many celebrated men, including Newton, Rousseau, Voltaire, Currier, Victor Hugo, Lamartine, and Renan, were born prematurely. The book, which is well indexed and gives numerous references to current literature, should prove useful.

*Premature and Congenitally Diseased Infants*. By Julius H. Hess. (L.D. London: J. and A. Churchill, 1923. (Med. Soc. pp. xi + 257, 12s.) Figures, 15s. net.)

*Non-Surgical Drainage of the Gall Tract*. By B. B. Vincigrat Lyon. (A.P., M.D., Philadelphia and New York: Lea and Febiger, 1923. (Med. Soc. pp. xvii + 650; 172 figures, 10 plates.)

with public health administration would be very much increased. One of the best known of these books is the *Handbook of Sanitary Law*, by Dr. B. BURNETT HAM, which was first published in 1899, and the ninth edition<sup>3</sup> of which is edited by Professor H. R. KENWOOD. Under various headings, such as nuisances, water supply, sewerage and drainage, housing, and food supply, the laws relating to the respective subjects are tabulated, and by a free use of cross-references a clear picture is placed before the reader. The first chapter contains a useful list giving definitions of terms used in particular Acts of Parliament, with in many instances (it is a pity it is not in all) the statutory authority for the definition. On page 5 it is stated that the local authority authorized by the Sale of Food and Drugs Act to appoint a public analyst is a county council or a county borough council. To this should be added "a quarter sessions borough having a population of 10,000 and over." Nearly fifty pages are devoted to the law relating to food supplies, in which the editor has brought together various Acts, orders, and regulations, the details relating to milk being very complete. The Sanitary Officers' Order, 1922, which relates to the appointment and duties of medical officers of health and sanitary inspectors, is given almost textually, and there is a very clear abstract of the Local Government and other officers' Superannuation Act, 1922. In a work which so admirably serves the purpose for which it was written it is a pity that greater care was not taken in revising the present edition and the correct titles of Acts of Parliament and other documents given. On pages 11 and 12 the Children Act, the Dairies, Cowsheds and Milkshops Order, the Factory and Workshop Act, and the Housing, Town Planning, etc., Act are all given incorrectly, although the proper designations are to be found on subsequent pages.

Only those who have to administer the law relating to the production and distribution of food can really appreciate the pitfalls which they have to avoid if success is to attend their labours. During a period of nearly forty years *Bell's Sale of Food and Drugs Acts* has been a safe guide for those who would escape them, and the seventh edition,<sup>4</sup> edited by Mr. CHARLES F. LLOYD, of the Inner Temple, has been brought as well up to date as seems possible when dealing with a subject with regard to which the Legislature and the central administering department of the Government appear to have no very settled policy; owing to this lack we have a constant output of Acts of Parliament, amending Acts, postponing Acts, departmental orders, amending orders, and rescinding orders in such quick succession that "order, counter-order, disorder" aptly expresses the present position. Mr. Lloyd has continued the general arrangement of previous editions, and some idea of its completeness may be gathered from the fact that although the principal Food and Drugs Act—that of 1875—contains only 36 sections, it is so fully annotated and there are so many references to legal decisions that more than 100 pages are devoted to this Act alone. As an instance of the extreme care and thoroughness which has been taken in annotating we may refer to Section 16 of the Act, which provides that an article may be sent to an analyst through the post "subject to any regulations which the Postmaster-General may make": the text of those regulations is given, thus saving much trouble and possible vexation to those concerned with the dispatch of samples. The amending Food and Drugs Acts, the Margarine Acts, and other statutes even remotely bearing on the subject, are considered with care and fullness. The text of the Milk and Dairies (Amendment) Act, 1922, is given in full, and there are many cross-references which cannot fail to be of service. Although the Milk and Dairies (Consolidation) Act, 1915, does not come into force completely until the end of 1925 it has very properly found a place in the appendix, which also

contains a very complete set of the circulars and memoranda of the Local Government Board and Ministry of Health with respect to the sale of food and drugs. In this connexion we suggest that it would increase the facility of reference if in future editions the editor would attach to the documents the number given to them by the Ministry of Health. The notes on some of the commoner forms of adulteration which Mr. R. A. Robinson, of the Middle Temple, contributed to previous editions are continued in the present and add to the completeness of the volume.

The student who is preparing for examination in public health will find Dr. AITCHISON ROBERTSON'S *Aids to Public Health*<sup>5</sup> of great use as a refresher. The matter is arranged after the manner of larger well known textbooks, the earlier chapters dealing with meteorology, ventilation, and water supplies, and the later with vital statistics and sanitary administration. The intervening chapters cover the ground very fairly and the information has been brought well up to date. The chapters on drainage and the disposal of sewage are accurately and clearly written, very good descriptions being given of the most modern methods of dealing with sewage. In the section on conservancy systems reference is made to the deodorant power of dry earth, but there is no mention of the nitrifying action of the earth, and it is to this property rather than any power of deodorizing that suitable earth serves a useful purpose when mixed with excreta. On page 150 the zymotic death rate is said to refer to the deaths from notifiable infectious diseases. Many years ago a great deal of importance appeared to be attached to the death rate from the "principal zymotic diseases," but these were not the notifiable infectious diseases, and nowadays the more progressive medical officers of health have no concern with zymotic death rates. We can recommend this little book to those for whom it is primarily intended—public health students.

#### TYPHOID-PARATYPHOID GROUP OF BACTERIA.

THE many different types of bacilli which, because of their similar behaviour towards ordinary laboratory tests, are arranged together as the typhoid-paratyphoid group, have been made the subject of a special research by Dr. A. HECHT JOHANSEN of the Copenhagen Institute, who has written a monograph<sup>6</sup> in English on their classification. Although for the last ten years a fairly consistent nomenclature has been followed in this country, Continental writers have often been unwilling to distinguish between certain strains which we in this country regard as distinct; this has led to considerable confusion, more particularly in translating from German authors. It is a relief, therefore, to find a familiar classification followed in this book, thus rendering it easy to compare the work of this author with that of our fellow countrymen.

The chief bacteria included in the group are, of course, the typhoid and dysentery bacilli, the paratyphoid bacteria, and food-poisoning organisms of the Gaertner type. These resemble each other very closely, and the different classifications which have been proposed in the past, based on the character of growth on media, fermentation reactions, and serological tests, are separately considered by Dr. Johansen and their limitations admitted. The greater part of the original work published in this book describes an attempt at classification based on agglutination and complement fixation reactions in conjunction with absorption tests. About a hundred different strains were studied, and the mass of experimental work recorded indicates that the typhoid, paratyphoid, and enteritidis organisms may be divided into eleven groups. The work would have gained in interest had the same laborious tests been directed towards the paratyphoid C bacillus and the atypical organisms about which there is so much dispute at present, but as it stands it provides a reassuring contribution to

<sup>3</sup> *Handbook of Sanitary Law*. By B. Burnett Ham, M.D., D.P.H. Edited by Henry R. Kenwood, C.M.G., M.B., F.R.S. Edin., D.P.H. Ninth edition. London: H. K. Lewis and Co., Ltd. 1923. (Fcap. 8vo, pp. xxviii + 244. 5s. 6d.)

<sup>4</sup> *Sale of Food and Drugs Acts*. By the late Sir William J. Bell, LL.D. Edited by Charles F. Lloyd. Seventh edition. London: Butterworth and Co., and Shaw and Sons, Ltd. 1923. (Crown 8vo, pp. xxv + 426. 15s. net.)

<sup>5</sup> *Aids to Public Health*. By W. G. Aitchison Robertson, M.D., D.Sc., F.R.C.P.E. London: Baillière, Tindall, and Cox. 1923. (Fcap. 8vo, pp. viii + 160. 3s. 6d. net.)

<sup>6</sup> *Classification of the Strains belonging to the Typhoid-Paratyphoid Group of Bacteria*. By A. H. Johansen. Copenhagen: Levin and Munksgaard. 1923. (Sup. roy. 8vo, pp. 206.)

the classification of these important but still ill defined groups of bacteria. The exhaustive tests advocated in this monograph are very time-consuming, and inspire one more the hope that some simpler method of study will one day be discovered.

The second part of the book describes experiments on the viridity of antiserum for complement. These were complicated researches which certainly throw light on the laws governing the fixation between antigen and antibody, but they do not add anything to our knowledge of individual members of the group, nor of the relationship of one organism to another. It is to be regretted that the manuscript was not better translated, for in many places the language is decidedly ambiguous.

#### THE HOME AND HEALTH IN INDIA.

The fruits of long experience and competent observation are gathered in Dr. KARE PLATT's book on *The Home and Health in India and the Tropical Colonies*. It is a manual of advice which will be particularly valuable to women going to these regions for the first time. The chapter on outfit and equipment is of first importance and should be studied before leaving this country. In choosing a home newcomers are inclined to be influenced by the beauty of a bungalow near a tank or surrounded by luxuriant vegetation, and they may learn by sad experience that the pleasures of the scenery are more than counterbalanced by the abundance of mosquitoes. The fly nuisance is well dealt with by Dr. Platt, and the dangers of disease conveyance and methods of protection are explained. As regards domestic sanitation, however, she seems to have a leaning to conservative methods rather than house drainage, on the ground that lack of intelligence on the part of native servants may make the latter a failure. But the newcomer would do well to remember the possibility of a sweeper's strike, which is a very serious matter for those who have not the benefit of a water carriage system.

A large part of the book is devoted to the health of the mother and child in India, and will be appreciated by the young wife. For those in outlying districts where medical attendance is not easily or immediately available, the chapters on tropical diseases, skin troubles, bites, and stings, will be of great service both in emergencies and for general guidance. Dr. Platt has been very happy in her clear and simple explanation of technicalities. She and her readers are alike to be congratulated on her success, and the book ought to find a place in the equipment of every young wife about to settle in India or the tropics.

#### NOTES ON BOOKS.

The second edition of Dr. FRIEß's monograph entitled *Electric Ionization*—the first was published in 1920—has appeared. In addition to a general overhauling and revision which has resulted in a considerable enlargement of the parts devoted to the statement of electrical facts and to the explanation of electrical terms, several additional chapters are given in connection with its application to the treatment of certain diseases. For instance, there is a special chapter on pyorrhea, another on endometritis, and so on. The work regards the actual application of ionization that its value as a textbook has been considerably enhanced, and those interested in this somewhat specialized branch of therapy will find much that is of value from the practical point of view. It is well presented and well printed; the illustrations are good and useful, and the index is sufficient.

*The Dominant Sex: A Study in the Sociology of Sex Differentiation*, by MATHIAS VAEHING, translated from the German by CEDRA PLATT, from the German work of Mathilde and Mathias VaeHING, has been admirably translated by EDEX and DUFFY. London: Baillière, Tindall and Cox, 1932. (Cr. pp. 216, 8s. net.)

FLEXNER (Senior Honorary Anaesthetist, Bristol Royal Infirmary) writes: "The dilator illustrated herewith is retained in position by the shoulders, and the legs B prevent the also nest from coming loose. The tendency of the dilator is well illustrated in the administration of nasal gas, by oral breathing during induction. The makers are Messrs. Down Bros., Ltd., 21-23, St. Thomas's Street, London, S.E.1."

Mr. WALTER G. HOWARTH, F.R.C.S. (London), has found the instrument here described useful in the excision of malignant growths of the pharynx, tongue, tonsil, and palate with the diathermic spark. It consists of a platinum knife embedded in a thin glass tube covered for the purpose of further insulation by thick rubber tubing. The cable is very light. The instrument has been in use for several years at St. Thomas's Hospital, and several advances have been made by Mr. Wain of the X-Ray Department. The instrument can now be obtained from Messrs. Mayer and Phelps, New Cavendish Street.

Dr. A. L. FLEXNER (Senior Honorary Anaesthetist, Bristol Royal Infirmary) writes: "The dilator illustrated herewith is retained in position by the shoulders, and the legs B prevent the also nest from coming loose. ## THE TREATMENT OF GENERAL PARALYSIS BY TRYPARSAMID:

### PENETRATION OF THE DRUG INTO THE CEREBRO- SPINAL FLUID.

THERE are many points of similarity in the pathology of sleeping sickness and of general paralysis. In both diseases there is an invasion of the brain by a specific organism, and it is therefore probable that a therapy that would arrest or cure the one disease would arrest or cure the other.

It is certain that cerebro-spinal syphilis occurring within the first few years after infection has yielded to treatment by mercury or arsenobenzol compounds, and, provided the treatment had been adopted before thrombosis of vessels and degenerative softening of the neuronic structures had occurred, surprisingly satisfactory results were obtained. Whereas in general paralysis, although arrests and even cures were announced as a result of intensive treatment by arsenobenzol compounds or their substitutes, either by intravenous injections of the drug or by intrathecal injections of salvarsanized serum, further experience only showed that a successful remedial treatment had yet to be found.

The question arises whether this difference in the results of treatment of these two forms of neural syphilis is due to a resistance of the organism, owing to a morphological latent form in the nature of a granule in general paralysis, or whether there is a specific organism which has acquired some means of resistance to these metallic poisons. For general paralysis, it is said, is unknown among races of people who have not been subjected to treatment. Experiments by Förster and Tomaschewski showed that apes could not be inoculated by brain tissue containing living spirochaetes, and Levaditi and others have brought forward many facts and arguments tending to establish the existence of two forms of spirochaetes—a neurotropic and a dermatotropic. It has been shown that a considerable percentage of infected people give a positive Wassermann reaction of the cerebro-spinal fluid and that in spite of effective treatment a certain proportion remain positive. It is probable some of these are the cases that eventually develop the late forms of neural syphilis.

How can this be explained? The blood and general lymphatic circulations may have received abundance of the spirillicidal agent, yet the positive reaction of the fluid indicates the existence of the organism in the tissue of the central nervous system. An explanation may be found in the fact that the organism has left the general lymphatic circulation which accompanies the vessels of the brain and entered the closed circulation of the cerebro-spinal fluid which irrigates the brain. Histological examination, in fact, shows that the spirochaetes lie in little foci actually in the nervous tissue. Their multiplication produces a toxin which escapes with the cerebro-spinal fluid along the perivascular spaces, thence into the subarachnoid space, setting up a meningo-encephalitis there. In sleeping sickness a similar meningo-encephalitis is set up by the toxins produced by the trypanosomes in the nervous tissue.

There is probably an anatomical reason why cerebro-spinal syphilis yields to treatment. It is that the specific organism which is causing the meningitis, perivascularitis, and endarteritis is located in the lymphatics which form a part of the general lymphatic circulation. The spirochaete is therefore accessible to the therapeutic agent. That that is so seems probable from the fact that in general paralysis and sleeping sickness inflammation of the endarterium does not occur. The inflammatory reaction in these diseases is in the perivascular sheath of veins and arteries, and not in the tunica adventitia. The cerebro-spinal fluid is a secretion of the choroid plexus, and there is evidence that the usual spirillicidal drugs either pass with great difficulty or do not pass at all through the choroid plexus. Such drugs as soamin and atoxyl, which were once used for the treatment of sleeping sickness and found ineffective, probably did not penetrate the cerebro-spinal fluid in the doses it was safe to administer. Likewise, as already remarked, experience showed that salvarsan and its substitutes were inefficient in the treatment of general paralysis. Indeed, the progress of the disease often appeared to be hastened by energetic treatment with this drug.

In the *Journal of the American Medical Association* (May 26th) the remarkable results of the therapeutic use of tryparsamid in neuro-syphilis are recorded by W. F. Lowry, A. S. Lowenhart, W. J. Blackman, and E. J. Hodge. The tryparsamid used in their work at Madison, Wisconsin, was supplied by the Rockefeller Institute. They state that "it is our clinical experience, largely borne out by histologic studies, that the demarcation between meningo-vascular syphilis and paresis is not very clear. Excepting the extremes of these conditions, the transitional point, or mean, is a matter of opinion." It is for this reason that I have set out above what I conceive to be the essential pathological difference.

The very successful results obtained by these investigators may be interpreted in two ways. First, it may be said that among their cases are included early forms of neuro-syphilis that were readily curable by mercurial inunction in the pre-salvarsan days and still more readily curable by modern intensive treatment. It might be argued also that some cases of general paralysis undergo spontaneous remission. However, this certainly does not account for the fact that "of the total of fifty-four cases of paresis studied, twenty-eight have been discharged from the hospitals and have been holding positions and earning a livelihood for themselves and their families for periods ranging from six months to two years."

The Wisconsin workers relied at first solely upon tryparsamid, but they found "that the additional use of mercury during the time of tryparsamid treatment resulted in more permanent improvement of the serologic findings as well as more rapid clinical improvements." Incidentally it may be asked whether this is not the same experience as with salvarsan. The treatment now adopted by them is as follows:

"To dissolve 3 grams of tryparsamid in 10 c.cm. of sterile freshly distilled water and to inject the total amount intravenously. This solution is given at intervals of one week and for a period of eight weeks. At the same time mercuric salicylate is administered intramuscularly in 1-grain doses. The mercury is given three days before the tryparsamid, and a total of nine such injections, alternated with the eight injections of tryparsamid, comprise a course." A rest is then given of from five to eight weeks, when a second course is repeated. After this second course and a period of rest, if there is continued evidence of activity or the case is still serologically positive, a third course is given.

A note of warning is sounded as to the danger of retinal affection, but other complications arising from arsenic are not mentioned. It would be interesting to know whether neuritis, dermatitis, and liver affections do not occur.

It has already been pointed out that there is an essential difference in the pathological conditions which would account for the one form of neural syphilis yielding readily to treatment, whereas the other (for the same reason as sleeping sickness) does not yield to treatment. I cannot agree with the following statement: "It is our clinical experience, largely borne out by histologic studies, that the demarcation between meningo-vascular syphilis and paresis is not very clear." Before hailing this new drug, combined with mercury, as a cure for general paralysis it will be necessary to have the results of independent observers who will not include all cases of meningo-vascular syphilis with mental symptoms in the group of general paralysis. In the summary, the claims of success are more restricted. "Clinical and serological improvement in early and violent cases of paresis is extremely striking. The recovery or improvement is not absolutely stable; but the use of mercuric salicylate with the tryparsamid tends to stabilize the improvement." The main question is this: Can tryparsamid intravenously injected penetrate the cerebro-spinal fluid and the tissues of the brain and by its direct or indirect influence kill or arrest the development of the trypanosome or spirochaete without injuring the nervous tissue?

In an article published in the *Journal of the American Medical Association* on June 2nd, entitled "Tryparsamid and its penetration into the spinal fluid," it is stated that "workers of the United States Public Health Service have now made available the results of an experimental investigation of the penetration into the cerebro-spinal fluid of tryparsamid and other arsenicals which is enlightening as to the mechanism by which the reported effects (previously

alluded to in general paralysis) are brought about." A heavy suspension of *Trypanosoma equiperdum* was injected into the cranial subarachnoid space of rabbits.

"No essential difference in behaviour towards arsenicals has been observed between *T. equiperdum*, *T. gambiense* and *Spirochaeta pallida*. Preliminary investigation demonstrated that trypanosomes thus injected would be recovered in considerable numbers.

"Trypanosomids and other arsenicals were then injected into the car vein of infected animals." After twenty-four hours a careful search was made in at least six different specimens of cerebro-spinal fluid taken from the various subarachnoid spaces of the brain and meninges.

"The absence of trypanosomes in these specimens was considered evidence of permeability of the membranes by the arsenical infection or of some trypanosoidal derelictive. Under these experimental conditions trypanosomids proved more effective than any other arsenical used. An amount which was only 4 per cent. of the minimal lethal dose was 87 per cent. efficient. Subinjection with 16 per cent. of its minimal lethal dose was 82 per cent. efficient."

"These experiments show that this arsenical preparation, probably by its penetration into the fluid, acts more efficiently than other arsenical preparations in destroying trypanosomes. We are told that the drug is "a white crystalline solid extremely soluble in water. It is odourless, tasteless, and possesses practically no local irritating action." Should further observations on an extensive scale show that a safe remedy for the arrest or cure of general paralysis and sleeping sickness has been found, it will be a great triumph for experimental medicine.

FREDERICK W. MORT.

## A NOTE ON THE "SO-CALLED PARKINSON'S MASK."

J. PARKINSON'S MASK.

THE peculiar after-effects or residua of epidemic encephalitis have given rise to an increasing study of everything appertaining to paralysis agitans. The name of Parkinson has thus become familiar to many who, a few years ago, might have hesitated before stating the exact disease with which it is associated. By utilizing the recognized synonym of paralysis agitans—namely, "Parkinson's disease"—we obtain a short and easy series of substantives and adjectives wherewith to describe the various signs and symptoms following epidemic encephalitis.

On the continent of Europe, where these residua have been even more common than in this country, this terminology has been adopted extensively. "The Parkinsonism," "Parkinsonism," "pseudo-Parkinsonism," and other modifications, are at the present time in use in medical papers. Their exact meaning differs somewhat with different writers. Some use the term for conditions other than pre-tremor or true paralysis agitans; others retain the expression "Parkinsonian" for the disease which Parkinson described, and use the term "pseudo-Parkinsonian" for other similar but distinct conditions.

There is thus a certain amount of confusion in the use of the terms.

In any case the adoption of this nomenclature has called attention to Parkinson's original *Essay on Shaking Palsy*, published in 1817, and all who have read it must admit that it deserves this tribute to its memory.

James Parkinson was a surgeon who practised in Hoxton; he wrote a number of small medical books in addition to his essay. He got into trouble in 1794 in connexion with the "pogrom plot," as it is described more at length in the *Dictionary of National Biography*. He was also a paleontologist and wrote a big book in three volumes entitled *Organic Remains of a Former World* (1804-1811).

described as "the first attempt to give a familiar and scientific account . . . of fossils." He was an original member of the Geological Society. He died on December 21st, 1824.

Thanks to the enterprise of the *Archives of Neurology and Psychiatry* (1922, vii, 681), this essay has now been again recently, and is available for anyone to read. On reading it again recently, I was surprised to find that it contains no allusion to the facial expression in paralysis agitans.

There is an excellent description of the tremor, and it is again recently, I was surprised to find that it contains no allusion to the facial expression in paralysis agitans.

There is an excellent description of the tremor, and it is again recently, I was surprised to find that it contains no allusion to the facial expression in paralysis agitans.

temporary cessation on voluntary movement; the stooping attitude; the hurried gait; the salivation. There are also statements which appear to refer to postural changes and rigidity, together with remarks on the supposed pathology and suggestions for treatment, but from first to last, there is no reference to the "facies."

This is the more surprising because, prior to the use of the term "Parkinsonian" in connexion with the residua of epidemic encephalitis, the only sign of paralysis agitans to which the author's name was commonly attached was the characteristic "facies"—the so-called "Parkinson's mask." It is, indeed, the irony of fate that, more than a century after his death, Parkinson's name should be particularly attached to practically the only prominent sign which he failed to record in his essay. It seemed to be a matter of some historical interest to find out when and where this term "Parkinson's mask" arose. With the assistance of the Librarian at the Royal Society of Medicine (Mr. H. E. Powell) an attempt has been made, and the following facts ascertained:

So far as we can ascertain, Charcot, in his many writings, in the middle of last century, was the first to emphasize the diagnostic importance of the immobile "facies" in paralysis agitans. We cannot find that any of the leading textbooks prior to this period make any reference to it. Whether or not Charcot himself first observed it seems uncertain. Ruge in the first edition of his *Textbook of Medicine* (1866, i, 629) writes: "According to Charcot the expression 'facies', but Charcot and Vulpian (Gaz. Hebdomadaire de Médecine et de Chirurgie, 1861-62, vols. 8 and 9) quote a case described by Oppolzer in the *Wiener medizinische Wochenschrift* for 1861, where he says 'der Gesichtsausdruck ist ganz apathisch.' This may possibly have drawn Charcot's attention to the sign.

It is thus probable that the pathognomonic facies of paralysis agitans was not recognized—at any rate, it was not recorded—until about fifty years after Parkinson's original essay was published. This is as surprising as that a shrewd observer like Parkinson should have omitted all mention of it. Is it possible that this particular feature of the syndrome was absent or less marked during the first half of the nineteenth century?

Such a suggestion might have seemed rather far-fetched a few years ago, but our experience of the effects of epidemic encephalitis shows that the different components of the syndrome which we call "post-encephalitic paralysis agitans" may each occur separately and almost alone, and that the particular region involved may be strikingly limited. Thus it is not uncommon to find the residuum following encephalitis in the form of the characteristic "facies" of paralysis agitans as the earliest and most striking feature; the extent to which the rest of the body is then affected may be exceedingly slight.

Even in pre-encephalitic paralysis agitans the facies may be absent for long periods. Moreover, diseases do change their type from time to time. This may possibly explain the curious oversight of this striking sign, not only by Parkinson who studied carefully, some cases, but by physicians turning the following half-century, who at least wrote about them.

The earliest record that I can find of the use of this term to describe a facial expression is in a paper by Gayer, in the *Archives de Physiologie* (1875, ii, Série II, 341). He there records what he calls an "affection encephalitique" which bears a striking resemblance to epidemic encephalitis. In this article the term "masque" is repeatedly used. Thus he writes: "Tout le masque est singulièrement affaissé." "Il n'a plus son masque facial si prononcé." "Le masque de la face s'est amoindri." It is interesting that this early use of the term should be in connexion with a case, not of paralysis agitans, but of an acute disease stimulating epidemic encephalitis in many respects. The evidence that we find of its application to the facies of paralysis agitans is in the article on this disease by W. Sinker in Pepper's *System of Medicine*, vol. 5 (1825). Two

years later Paul Richer (*Nouv. Icon. de la Salpêtrière*, 1888, p. 213) writes of the facial expression in paralysis agitans, "C'est masque vide, dont la vie semble absente."

The term "facial mask," or mask-like face, applied to paralysis agitans, thus seems not to have been used at all generally until after Charcot's time. It has the advantage of being brief, though not an apt description of the condition.

#### *The Earliest Use of the Term "Parkinson's Mask."*

So far as our investigations go, the first use, in print, of the term "Parkinson's mask" is found in the first edition of Osler's well known *Textbook of Medicine*, 1892. Mr. Powell has searched through all the leading textbooks from 1817 to 1892 and can find no previous use of Parkinson's name in this connexion.

The actual expression which Osler uses is rather curious, "the so-called Parkinson's mask." This was repeated in each succeeding edition down to 1916. To one as familiar with the original works of the past as Osler was the fact that Parkinson had not described the facies of paralysis agitans must have been well known; hence the form of his expression—"the so-called Parkinson's mask." It seems, therefore, probable that about the early nineties the term "Parkinson's mask" had become current amongst certain medical teachers in certain parts of the world, and that Osler first gave it official recognition as a concise\* and convenient label for the student.

It may be said that in using the term "Parkinson's mask," we merely mean the mask-like face seen in Parkinson's disease, and as such the term is quite warranted. When, however, the term "Parkinsonism" is applied, as it frequently is at the present time, to post-encephalitic residua which may consist of nothing but an immobile face with certain mental and moral changes in character, it is historically inaccurate.

In conclusion, I desire to thank Mr. Powell for his valued help, and to take this opportunity of pointing out to my colleagues living in the provinces the many valuable services which the Royal Society of Medicine places so generously at the disposal of those Fellows who are unable to make frequent personal visits to the library.

ARTHUR J. HALL, M.A., M.D., F.R.C.P.,  
Professor of Medicine, University of Sheffield.

#### EPSOM COLLEGE.

THE annual general meeting of the governors of Epsom College was held at the office, 49, Bedford Square, W.C., on June 29th, when the treasurer, Sir HENRY MORRIS, was in the chair.

The names of the successful candidates for foundation scholarships were announced as follows: Thomas M. Newton, Jeffrey O. Timms, James D. Johnston, Irwin J. McGhie, Denis A. Sanford, H. Vincent Adcock. The successful candidate for the ordinary pensionership was Adelaide Lynch.

In submitting the annual report of the Council, the chairman drew attention to the loss the College had sustained by the death of Mr. Clement Locke Smiles, as well as by the retirement from the Council of Mr. Walter Archibald Propert, the grandson of the Founder of the College. The governors were also informed that Mr. W. Douglas Crossley, who entered the College as a master in September, 1888, and was appointed bursar in September, 1890, was about to retire, after a service to the College of practically thirty-five years. The chairman paid a tribute to the zealous and efficient way in which Mr. Crossley had carried out the duties of his office during that long period. The chairman further reported that Mr. Bluett, one of the honorary auditors, had died since the last annual general meeting, and that the Council proposed that Mr. Norman C. King, the registrar of the General

Medical Council, should be appointed an honorary auditor in his place. The chairman also drew attention to two pension funds recently instituted, and mentioned that the Council had decided to propose that, in consequence of the increased cost of living, amendments in the by-laws should be made to permit a somewhat larger income than hitherto held by persons wishing to become candidates for various pensionerships—namely, £100 a year instead of £60. He stated that steps had been taken to begin at once the work of rebuilding the nave of the chapel in harmony with the new chancel, in spite of the fact that the funds in hand were not sufficient for the purpose, and he urged all friends of the College to do their best to secure contributions.

In the report to the governors, the Council expressed its thanks to the various honorary local secretaries, the British Medical Association, and other friends who had assisted the Royal Medical Foundation attached to the College by obtaining donations and subscriptions, as well as to the editors of the *British Medical Journal* and *Lancet* for many services kindly rendered. The Medical Insurance Agency of the British Medical Association had again sent generous contributions, for which the Council was grateful. For many years it had been customary to elect as vice-presidents those who had collected the sum of £1,000, and as the Rev. Walter J. Barton, the late head master, had succeeded in completing this sum, the Council proposed that he should be elected a vice-president of the College.

After the adoption of the annual report and accounts, formal business was transacted, including the re-election of members of the Council and auditors, and the adoption of new by-laws. A cordial vote of thanks to the chairman was proposed by Dr. Raymond Crawford, who drew attention to the valuable services rendered to the College by Sir Henry Morris as treasurer. This resolution was seconded by Mr. Hollis Walker, K.C., and carried with acclamation.

#### BIRTHDAY HONOURS.

THE deferred list of honours granted on the occasion of the King's birthday was issued as a supplement to the *London Gazette* of June 29th. The following are among the names of those upon whom honours have been conferred:

##### *Baronetcy.*

Major-General Sir Anthony A. Bowlby, K.C.B., K.C.M.G., K.C.V.O., F.R.C.S., President of the Royal College of Surgeons of England; Consulting Surgeon to St. Bartholomew's Hospital.

##### *Knighthoods.*

George Francis Blacker, C.B.E., M.D., F.R.C.P., F.R.C.S., Dean of University College Hospital Medical School.

Ewen J. Maclean, M.D., F.R.C.P., F.R.C.S. For services to the Ministry of Health in Wales. Dr. Maclean was formerly chairman of the Representative Body of the British Medical Association, and presided over the Annual Representative Meeting in 1911 and 1912, when held in Birmingham and Liverpool respectively.

##### *C.B.E. (Civil Division).*

Lieut.-Colonel John Southey Bostock, M.B., Ch.B., Director of Medical Services, Ministry of Pensions.

The distinction of C.B.E. (Civil Division) is also conferred upon Mr. Ernest T. Nethercoat, President of the Pharmaceutical Society, in recognition of his services in connexion with the Dangerous Drugs Regulations.

THE second International Congress of Comparative Pathology will be held in Rome from October 7th to 14th. The subscription is 40 lire. Further information can be obtained from Professor Perronetto, 40, Corso Valentino, Turin.

THE thirty-eighth annual meeting of the Caledonian Medical Society was held on June 29th in the rooms of the Aberdeen Medico-Chirurgical Society. The President, Dr. D. Rorie, D.S.O., took as the subject of his presidential address the career of Dr. George Boswell, who was surgeon to King James VI of Scotland. The meeting was largely attended, and at the dinner the same evening seventy members and guests were present. It was arranged to hold the next annual meeting of the society in Liverpool under the presidency of Dr. David Smart.

\* In Fagge and Pies-Smith's *Textbook of Medicine* (fourth edition, 1, 1877) the words are, "The features are immobile and the face has a mask-like expression, like a mask, as Parkinson described it." The name Parkinson is evidently a "lapsus calami" for Charcot, which occurs in previous editions.

SATURDAY, JULY 7TH, 1923.

CANCER: ITS CAUSES AND TREATMENT  
BY RADICAL

Of all the hypotheses which have been advanced from time to time to explain the causation of cancer, only one receives any measure of support from the experimental studies of recent years—namely, the original theory of Virchow that tumours are caused by irritation, chemical or physical. This seemed the most likely interpretation of the facts observed by those who studied the clinical manifestations in the days before methods of inducing cancer in animals had been discovered; it has been sustained by the evidence derived from the experimental production of cancer following such irritants as tar, paraffin, and x rays. In a British Medical Association Lecture published this week (p. 1) Dr. Archibald Leitch discusses several different agents which have been shown to be capable of producing cancer in animals; all are of an irritating nature, being foreign to the cells of the body, and invoking in them the familiar response—proliferation and increased cellular activity.

Evidence derived from experimental inquiry into the causes of cancer has not only brought support to the doctrine that cancer follows chronic irritation, but has also very considerably narrowed the issues by demonstrating that certain irritants are very potent agents in producing tumours, whereas others have not been found to possess carcinogenic properties, to use the term the lecturer has devised. The irritant is therefore in a sense specific; it evokes a response in the cells which is at first similar to that aroused by other stimuli, but later, on account of its peculiar nature, leads to the anarctic and progressive proliferation that we call cancer. The evidence is that certain irritants easily produce cancer, while others do not.

A second fact which the experimental study of cancer has brought to light is that the specific irritant produces cancer only in certain animals, and only in the susceptible tissues of these animals. Thus only particular races of rats can be infected with spiroptera carcinoma, and in those which are susceptible, tumours develop most rapidly in the stomach and tongue, but are unknown in the oesophagus; cysticercus sarcoma does not affect mice, and even certain strains of rats are refractory to this tumour-producing agent. Dr. Leitch has failed to produce far cancer in rats or guinea-pigs by the employment of a method which readily succeeded in mice. He had succeeded in producing cancer in mice by applications of paraffin, but failed in similar experiments on rats, guinea-pigs, and rabbits. Again, cancer common affliction of early radiologists, but no one has yet succeeded in producing epithelioma in animals by the application of x rays. It seems, therefore, that there must be not only a specific type of irritant, but also a peculiar cellular susceptibility in order that cancer should follow irritation.

Another important fact made clear by the experimental studies Dr. Leitch passed in review is that a considerable space of time may elapse between the

action of the irritant and the appearance of the neoplasm. A careful study of human cancer has often failed to reveal any recent antecedent irritation, but sufficient consideration has not been given to the possibility that a bias towards malignancy may be imparted to cells by some previous, and even distantly previous, irritation. That this may be the case is shown by Dr. Leitch's experiments with tar cancer, for he has observed that even if he stopped the applications of tar before there was any sign whatever of neoplasia, "in due course warts appeared and the phenomena of malignancy were unfolded just as before." The possibility that a particular tumour has followed the action of an irritating agent cannot be dismissed because the irritant has not been detected immediately prior to the appearance of the growth, for it may have been present in the past, and, though absent for some time, have transmitted to the neighbouring cells the fatal tendency to malignant proliferation.

Experiment has shown that cancer is not essentially a disease of ageing tissue; the reason why this disease more frequently occurs with advancing years is capable of another explanation than that the cells are manifesting senile changes. Dr. Leitch made two parallel series of experiments, using in one set adult mice and in the other mice all under six weeks old, and found that, after the application of tar, neither in yield of tumours nor in rate of tumour growth was there any appreciable difference between the two. The essential point may be the length of time the causal agent is in operation. Since in most instances this requires a protracted period, it becomes obvious why cancer is usually a disease of middle or old age.

To the pathologist it is of great interest to notice that after the application of paraffin to mice in some cases carcinoma and in other cases sarcoma developed in approximately the same time. Thus two very different kinds of tumour can be produced by the same agent, according to whether the irritant sub-stance affects chiefly the epithelial or connective tissue cells. It is not claimed that the irritant is necessarily the actual cause of the cancer; as Dr. Leitch observes, the carcinogenic agents may only be "the mediators," and not the proximate causal factors of the disease. All that is claimed for these tumour-producing agents is that they bring about a pathological state of the tissues, and that on this prepared soil the undermined causal agent of cancer can then exert its action. Still, it is curious that both carcinoma and sarcoma should follow the application of paraffin after approximately the same interval of time.

The fact that after a tar epithelioma has been extirpated from a mouse subsequent applications of tar do not induce any further tumour is an observation which may prove to be of great practical importance. After the removal of a spontaneous tumour from a mouse Dr. Murray found that the animal did not show any neoplastic response when afterwards subjected to painting with tar. This suggests that the occurrence of one form of cancer in an individual "protects" the body in some way against the occurrence of another. Dr. Leitch warns us against hasty conclusions from these experiments, and the result of further researches along these lines will be awaited with great interest, for they seem to hold out a promise of the justification of the optimistic spirit in which Dr. Leitch concludes his masterly review of the experimental inquiry into the causes of cancer.

His lecture is wholly concerned with the etiology of cancer, unless it can be said that Dr. Murray's

observation quoted above gives support to the surgical doctrine of early and complete removal. But cure is only less important than causation, and here it is satisfactory to note some hopeful signs. The treatment of cancer by radium, for example, is based on theoretical principles which encourage a hopeful attitude. As has been pointed out in the last two annual reports of the Radium Institute, the effect of radium irradiation upon any living cell, if of sufficient intensity and permitted to act for a sufficient length of time, shows three phases. First, there is an increase of cell activity, accompanied, it may be, by proliferation; secondly, there is an arrest of cell activity; and finally, degeneration and destruction of the cell. These three phases merge into each other, and no hard and fast line can be drawn between them, for the transition from stimulation to destructive irradiation is simply one of degree, depending entirely upon the intensity of the stimulus. It has been established that all cells are more vulnerable to irradiation when in a state of active nuclear division, and a pathological cell is much more susceptible than a normal to irradiation, so that a stimulus which would act only beneficently on a normal cell may prove destructive to an abnormal one. Successful radium therapy is dependent on the correct appreciation of these facts. Thus, if the dose be incorrectly calculated, and be excessive, destruction not only of the pathological but also of the normal cells occurs, resulting in great loss of tissue, with the formation probably of an intractable ulcer or fistula. On the other hand, if the dose be too weak, the pathological cells may be stimulated to activity, with consequent rapid increase in the size of the growth.

The paper by Drs. Donaldson and Canti on fifty cases of carcinoma of the cervix treated with radium (p. 12) affords an illustration of the care which must be taken in estimating the dose of radium rays necessary and in its application. In both respects they make valuable contributions to knowledge. They have sought by experiment to ascertain the proper dose, and incidentally have arrived at the conclusion that with the quantity of radium employed by them a continuous irradiation for twenty-four hours is much more effective than an application for eight hours thrice repeated. No extravagant claims to curing cancer are made by these authors, but they demonstrate once more that patients undoubtedly derive benefit from this form of treatment, in that the distressing symptoms of hæmorrhage and vaginal discharge often disappear, and ulceration may be diminished. They point out also that in operable cases a preliminary application of radium causes the disappearance of fungating growths or ulcers, "so that the risk of infection and of implanting new growth from the cervix at the time of incising the vagina is markedly diminished." The amelioration of symptoms which follows radium treatment was shown to be accompanied by definite histological changes; all the cells in close proximity were killed, whereas on those in the zone beyond this the irradiations did not seem to have an immediate lethal effect; about the third day, however, the chromatin of the cells was breaking up into droplets; on the third and fourth days a large number of cells still further away showed marked activity. A series of definite changes occurred in the carcinoma cells, leading eventually to their complete destruction, whereas the normal cells were less vulnerable, and in the uterine musculature local atrophy and fibrosis only took place at a later date. The treatment of cancer by irradiation

is still in its infancy; general principles have yet to be firmly established, an effective technique evolved, and correct dosage determined by experiment.

The two papers published in the JOURNAL this week illustrate how the problem of cancer is being studied from widely different points of view. The patient and exhaustive inquiry into the etiology of cancer has defined certain types of carcinogenic agents and showed that they only act on certain types of cell; slow but definite progress is made towards the ultimate goal of the cure of cancer by the cautious experiments carried out with irradiation.

The public is waiting for a startling discovery of the cause of cancer or some dramatic invention for its cure. This may, of course, be achieved in the future, but in the meantime it is reassuring to realize that if the problem of cancer is viewed in its natural perspective, and its dimensions, positions, and relations thoughtfully considered, it becomes obvious that the tide of knowledge is rising steadily and irresistibly.

For while the tired waves, vainly breaking,  
Seem here no painful inch to gain,  
Far back, through creeks and inlets making,  
Comes silent, flooding in, the main.

### THE NEW HOUSE OF THE BRITISH MEDICAL ASSOCIATION.

THE British Medical Association has acquired a fine building in Bloomsbury for its future headquarters. If a change was to be made—and undoubtedly a change had become necessary—members of the Association will, we believe, be practically unanimous in agreeing that the choice of locality has been happy. Bloomsbury has been slowly undergoing a transformation from an area of somewhat dingy respectability into the academic quarter of London. The change began when the British Museum was built towards the southern part of the district and University College a little beyond its northern border. The British Museum has been enlarged northward to almost twice its former dimensions; University College has extended mightily to the south and east. Some eleven acres of the central part, have been bought by the Government for the headquarters of the University of London and perhaps for King's College. A site has been found and cleared for the Imperial School of Hygiene at the western side of the district, and the British Medical Association is now to establish itself on its eastern edge.

The building which the British Medical Association will in future occupy is of singularly gracious proportions, and, while thoroughly individual, recalls memories of Kensington Palace and Hampton Court, and so of the genius of Sir Christopher Wren, who has found a successor in Sir Edwin Lutyens, the architect of our new building. The whole design has not been completed, but arrangements are being entered into which will enable the Association in due time to carry out any extension which may be considered necessary. The building is approached from what is becoming one of the principal thoroughfares of London, leading from the terminuses of the Northern Railways to the modern centre of London. But it stands back in its own quadrangle. Of the general appearance of the façade and of the quad so far as it has been completed an impression can be gained from the picture printed at page 33. A good deal must be done to the interior before it can be fitted to the purposes of the Association, and for this

the cordial co-operation of the distinguished architect, who has shown great interest in the project, has been secured. The building, however, which was erected as a college for the Theosophical Society, already provides much of what the Association needs; it has, for example, a large hall which will seat more than 500 people, or over 250 with desks, as for a Representative Meeting. The lease is for 200 years, and the terms secured by the Association must be regarded as very advantageous.

A change from its present premises was forced upon the Association by the growth of its work, especially in the Medical Department. The existing building was very substantially built, and is of course a most valuable asset, but it had become too small, and all the amenities the Association desires to provide for its members have been diminished, with the exception of the Library, which remains as the only room for the use of members not engaged strictly on Association business. The accommodation of the Library, too, had proved too small; the new building will enable excellent provision to be made for it, common rooms to be set apart for members, and ample office accommodation for the Medical Secretary's Department, the Financial Department, and for the Editorial Department. It is hardly necessary to say that the resolution to remove was only reached after very anxious consideration, but, as we have said, the necessity was obvious to all engaged in the central work, whether officers, members of committees, or officials.

The Association is, we think, to be warmly congratulated on its good fortune in acquiring a building which, even so far as it is at present completed, might almost have been designed for its purposes.

#### GUYS' HOSPITAL MEDICAL SCHOOL.

On July 2nd H.R.H. the Prince of Wales, President of Guy's Hospital, visited its famous Medical School for the purpose of opening the new anatomy, biology, and physics departments. This ceremony signified the completion of the rebuilding of the whole school during the twenty-six years that have passed since the first block was opened by King Edward VII (then Prince of Wales) in 1897. The total cost of rebuilding the various departments has been upwards of £100,000. The latest extension occupies an area of 4,000 square feet; it consists of five floors, each communicating with the principal staircase of the main block. By transferring the physics department from its former site to the new building, space has been freed for biochemical research within the department of chemistry, and in designing the new quarters for the departments of anatomy and biology special accommodation has been set aside for research. On Monday afternoon the grounds of the hospital were filled with a very large company, who gave the Prince a warm welcome on his arrival accompanied by Viscount Goshen, treasurer of the hospital, Mr. H. J. Waring, Vice-Chancellor of the University of London, Sir Cooper Perry, Principal Officer of the University, Mr. H. L. Eason, superintendent of the hospital, Professor J. B. Johnston, dean of the medical school, and the senior members of the hospital staff. The ceremony took place in the "park," on the steps leading to the extension. After the treasurer had offered a formal welcome to His Royal Highness, the dean read an address briefly recounting the history of the reconstruction of the school, and expressing the hope that other benefactors would come forward in the future to relieve the school of its incumber of debt and enable it to carry on its work in a manner worthy of the traditions of Astley Cooper, Bright, Addison, Gill, and

Wilks. The Prince of Wales expressed his pleasure at visiting Guy's to take part in celebrating this important event, and unlocked the door of the school with a gold key handed to him by Mr. W. J. Walford, architect of the extension. Dr. John Fawcett (senior physician) proposed, and Sir Alfred Fripp (senior surgeon) seconded, a vote of thanks to the President, who then made a brief tour of inspection of the new buildings. At the end of the formal ceremony a garden party was given by the governors and medical staff in the pleasant grounds of the hospital, and the laboratories, museums, college, the Henriette Raphael Nurses' Home, and the wards were visited by large numbers. Together this was a red-letter day in the annals of Thomas Guy's great foundation. The medical school has now been rebuilt, with ample accommodation for teaching and research. The next need is an adequate endowment fund. As the President of the hospital well said on Monday, science and industry are not enough; to light

#### THE MAYOS AND THE MAYO CLINIC.

The discussion at the Section of Surgery of the Royal Society of Medicine last week on the surgery of the hepatic and common bile ducts is reported elsewhere in this issue (p. 18), and a full note of the paper with which the discussion was opened by Dr. William Mayo will be found at page 7. In the evening Dr. Mayo was entertained by the Section at dinner at the Hotel Cecil. Mr. James Berry, President of the Section, who was in the chair, gave the health of Dr. Mayo and sketched the origin of the Mayo Clinic at Rochester, Minnesota. The father of Dr. William and Dr. Charles Mayo was born in the neighbourhood of Manchester and was a student of Owens College; with his Scottish wife he went out to America and settled in the village of Rochester, which is within the region of the Mississippi Valley and therefore subject to devastating tornadoes. Such a catastrophe destroyed the village in 1883, but left the church standing; a religious sisterhood, in thanksgiving for the preservation of the church, founded, at the suggestion of Dr. Mayo, the small hospital of St. Mary's, and it was under their father's tuition that the two young men received their first introduction to surgery. Gradually there grew up under their hands a great clinic which had done much for the advancement of surgery and had been visited by many surgeons from many lands. Mr. Berry went on to speak of the readiness of both brothers to make themselves acquainted by personal visits with the methods of surgeons in all countries, and of the enthusiasm and indomitable energy with which they have carried on their own work at Rochester. Mr. Berry concluded by expressing the hope that the Mayo Clinic would continue to flourish after its founders had left it. Dr. William Mayo in his reply said that the permanency of the clinic was a matter to which he and his brother had given much thought. If it was to live the clinic must, they realized, command the services of men of ideas and training, and these men should be afforded adequate opportunities to perfect their own methods and to keep themselves fully informed of every advance of surgery elsewhere. To meet these fundamental requirements he and his brother had from an early stage put aside out of the fees they received one half, with the intention that this money, received from the people, should be returned to them by providing facilities for research and for the education of surgeons; in this way the people would be repaid, since they would be able to command the services of better surgeons. Funds were also accumulated from the surplus of the clinic. The staff numbered altogether 128, and every member of it, including the chiefs, was paid by salary. In this way a fund of about eleven million dollars had been accumulated,

partly by the annual payments from the sources mentioned and partly by the interest on investments. In order to ensure permanency it was resolved to associate the clinic with the University of Minnesota. The fund had been handed over to a board of eleven persons, six elected by the staff and five by the university. He passed on to speak of the importance of a close co-operation between English-speaking peoples, not only to ensure the advance of surgery but also, and chiefly, for the progress of thought in all nations. The common possession of the English tongue meant something more than speaking the same language; it meant thinking in the same way. There was fundamentally a unity of purpose and of ideas; it remained to ensure the full realization of this unity. Sir Berkeley Moynihan gave the toast of American surgery in a brilliant speech, in which he sketched the early history of surgery in England and in America, and the intimate ties which from the earliest days of American independence had existed between surgeons in the two countries. If an attempt, he said, were made to enumerate the characteristics of American surgery they would be found to be perfection of technical achievement, integrity of statement, fertility in new suggestions, and readiness to receive new ideas. The profession in America was unafraid of new adventures in action or thought, and in American surgery none held higher places than Dr. William Mayo and his brother. The toast was acknowledged by Dr. Donald C. Balfour, a member of the Mayo Clinic at Rochester, who gave a brief account of the efforts made, and in part completed, to improve the organization of medical education in the United States.

#### EARLY MENTAL TREATMENT AT A GENERAL HOSPITAL.

At Middlesex Hospital on June 28th, two new wards, for men and women respectively, were formally opened for the treatment of functional disorders of the nervous system. These wards are to be worked in co-operation with St. Luke's Hospital for Mental Diseases, and the cases received will be under the treatment of the medical staff of St. Luke's and will be attended by St. Luke's nurses. This is believed to be the first instance in this country of an alliance between a general hospital and a special hospital for nervous disorders. The two institutions are to share funds, material, experience, and the services of the staff so far as may be necessary, and all the resources of a general hospital in the way of special examinations and of medical and surgical treatment will be available for these patients. Although the wards are for the reception of early mental cases which require in-patient treatment, it is not intended, nor would it be possible, to admit cases of insanity or mental deficiency, or cases of a kind which might cause annoyance to other inmates of the hospital; the patients in these wards will be under no more compulsion than those in the general wards. It is hoped that although the wards are small, and the cases treated must be few, the mere establishment of the wards will do something to break down the prejudice whereby mental trouble is severely isolated from all other human infirmities. The chief advantage of the arrangement will be that the environment of a general hospital is likely to react favourably upon patients and prospective patients, because such an institution will be approached by the patients with less hesitation and misgiving than a special mental institution often excites. The Earl of Athlone, Chairman of the Middlesex Hospital, welcomed the few persons present, chiefly members of the staffs of the two hospitals concerned, and extended a special greeting to the representatives of St. Luke's. He remarked that the importance of this interesting reform in hospital procedure was not to be

measured by the number of beds at present available, but by the fact that the principle of co-operation between a general and a special hospital of this kind, several times mooted, had now taken practical shape. Mr. A. C. Powell, treasurer of St. Luke's, said that there was a very great future for such co-operation. He remarked upon the fact that Middlesex and St. Luke's came into existence almost in the same year, and the history of St. Luke's indicated the rise and progress of the new spirit in regard to mental disorder. Formerly the word "lunatic" was commonly applied to cases received at that hospital, but the word had now completely disappeared; the change was not a mere polite convention, but was significant of a new outlook, to which the departure at the Middlesex bore further witness. Other speakers added a few congratulatory words, and Dr. O. Hubert Bond expressed the interest of the Board of Control in this movement. He remarked that at all the great general hospitals of this country there had hitherto been an impervious screen, whereby all mental cases were banned from their doors. It was a matter of profound interest, therefore, to find this association of Middlesex and St. Luke's, and he looked forward to the example being followed, if not by every general hospital, certainly by all the great teaching hospitals of the kingdom. The visitors afterwards inspected the wards; each contains accommodation for two or three patients; a special effort has been made to suggest cheerfulness in decoration and furnishing, and the appearance is very comfortable and homelike. The wards are in a part of the hospital away from the general wards and their approaches, and they form a self-contained unit, with sitting room, kitchen, and store cupboards. Border-line cases will also be treated in an out-patient department.

#### THE LABORATORY DIAGNOSIS OF VENEREAL DISEASES.

THE first edition of the Medical Research Council's Report (No. 19) entitled "The Laboratory Diagnosis of Gonococcal Infections and Methods for the Detection of *Spirillum pallidum*" was issued in September, 1918, and proved to be one of the most useful of the reports upon pathological methods, but it has been out of print now for some months. A revised edition<sup>1</sup> has now been published, and though it follows closely the original plan it contains some new features and is excellently illustrated. Its object is to describe reliable methods for the laboratory diagnosis of gonococcal infections and to explain the technique of dark-ground illumination and the staining reactions which may be employed for the identification of the syphilis spirochaete. The first part, which deals with gonorrhoea, discusses the localities which should be examined for the presence of gonococci, describes the methods to be employed for the identification of the gonococcus in film preparations, advises on methods for the cultivation of the gonococcus, cautions against the procedure employed for the production of a focal gonococcal reaction, and considers the advantages, disadvantages, and limitations of the complement fixation test. The descriptions of the most satisfactory methods of preparing culture media for this delicate organism are detailed and explicit, and four different methods for carrying out the notoriously difficult complement fixation test are given. One of the best features of this part of the report is the frank discussion of the value of the evidence which may be derived from these different methods of investigation. In the second part of the report Mr. Barnard explains in simple language the principles underlying observation by dark-ground illumination and describes methods for setting up the apparatus. This was looked upon as one of the most useful sections of the first

<sup>1</sup> H.M. Stationery Office, or through any bookseller. Price 1s. 6d.

technical difficulties of this branch of microscopy. Mr. Barnard describes a method he has recently devised for differentiating between *S. pallidum* and other spirochæmata by employing an agyricose graticule which provides a scale in reference to which the spirochæmata under observation may be measured. Dr. Dobell contributes the final section on other methods of demonstration of spirochæmats—namely, stained films, Indian ink and Congo red methods and silver nitrate methods—and emphasizes the precautions which must be observed in order to secure satisfactory preparations. His argument on the correct nomenclature of the organisms, commonly referred to as the syphilis spirochæmæ, leads him to the conclusion that its correct name should be *Spironema pallidum*.

**BOTULISM.**

A study of the epidemiology of botulism, by Drs. Geiger, Dickson, and Meyer, has been published in Bulletin No. 127 of the United States Public Health Service. In view of the admittedly great difficulty—perhaps we might say impossibility—of obtaining an exact and exhaustive record of the occurrences of botulism, statistics of incidence are hard to interpret. This remark applies equally to rates of fatality, geographical distribution, and attribution to particular articles of food. In spite of these obstacles the investigators have collected some important data. The most detailed inquiry related to the Yakima Valley district of Washington. A careful survey demonstrated that within five years 7 outbreaks of human botulism, 27 outbreaks in domestic fowls, 26 in horses, 3 amongst cattle, and 1 amongst pigs had occurred. Of 26 human cases in the State of Washington, 18 were fatal. Home-canned corn, asparagus, and spinach were incriminated, and in one case commercially canned evaporated milk seemed to be responsible. Thirty of the outbreaks studied—52.9 percent. of the available data—were verified bacteriologically. Regarding the relative proportions of the two types of organism, Type A has been isolated 38 times and Type B 13 times. In 11 outbreaks the diagnosis was established by the demonstration of the toxin of *B. botulinus* in the remnants of the incriminated food. The popular idea that food must always be visibly spoiled in order to be toxic is not entirely supported by the available observations, although in a majority of instances some abnormality was recognized. Instances of tinned beans, tinned spinach, and tinned minced olives occurred where *B. botulinus* is a soil parasite in no change was noticed. The frequent occurrence of botulism in the southern section of California is apparently closely connected with the distribution in nature of the spores of the bacillus. A short account of the observations made by Professor K. F. Meyer in California, and also in this country, where he found *B. botulinus* five times in 64 samples of English soil, was given in the course of a review published on June 22 (p. 932) of Dr. Gerald Leighton's book on *Botulism and Food Preservation*.

INTERNATIONAL INDUSTRIAL HYGIENE.

The International Labour Organization for Industrial Health is an offshoot of the League of Nations. There exists in the public mind some considerable confusion as to its constitution and real function, and many of those who are better informed about its objects seem to have had hazy notions respecting the details of its activities. It was therefore a happy conception on the part of the League of Nations Union to bring together lately in conference representatives from authoritative bodies, interested in promoting industrial health and safety, and accredited in

representatives of the International Organization itself. A report of the conference appeared in our last issue (p. 1108). Its aim was by means of discussions and explanations to produce a better understanding of the work carried on in Geneva and of the ways and means by which the efforts and objects of the bodies particularly interested can be assisted by a co-ordinating centre. Among the members of the medical profession present at the various sessions were Sir Thomas Oliver, Dr. J. C. Bond, Dr. W. F. Dearden and Dr. Alfred Cox, representing the British Medical Association, Dr. D. McKail, Dr. T. Watts, M.P., and Dr. W. H. E. Oxley, representing the association of Certifying Factory Surgeons, Dr. T. M. Legge, Professor E. L. Collis, Dr. F. E. Fremantle, M.P., Dr. C. S. Myers, Dr. W. Winfield Cullis and Dr. R. Legge (University of California). The scheme devised by the promoters was to select for discussion four of the principal industrial health problems now before the public; to have these introduced by well known British experts; to bring out under each heading how the International Organization could be useful. Mr. Harold Grimsbury, who occupies the position of Chief of the Diplomatic Section of the Central Office, was present at all the sittings and, during the course of the discussions as well as in a preliminary address, very ably fulfilled his particular task of making the situation quite clear so far as the International Organization was concerned. He pointed out that this body was not an amalgamation of Trade Unions or Societies, but held place as a well defined unit in the League of Nations constitution established by the Treaty of Versailles. Its function was to secure by international action the adjustment of conditions of labour throughout the world to the requirements of justice and humanity; its constitution was made up by membership of subscribing States, at present fifty-four in number. At periodical conferences to which each State sent four delegates—one representing employers, one representing workers, and the other two directly representing the Government concerned—draft conventions were formulated, recommendations with a view to co-ordinating legislation in member States were drawn up, and scientific Commissions of Investigation were appointed. He explained how the permanent staff at Geneva, under the supreme direction of M. Albert Thomas, collected information from all quarters, both for the purposes of the conferences and for the use of subscribing States, and added that much of this would be available to properly accredited associations who cared to make application. He also intimated that the magnificent library of the Organization would be at the service of any properly accredited representatives of such associations visiting Geneva. Though no resolutions were brought forward, the conference seemed much impressed with the present and future usefulness of the International Organization.

TO HARROGATE BY PULLMAN CAR.

first four years ago, in a note on Harrogate and its "One sure, if another successful efforts then being made to improve the organization and equipment of British spas and bring their claims more prominently before our own countrymen." The revival of Continental watering places since 1919 makes it desirable once again to remind the British medical profession of the advantages of our home health resorts, and to draw attention to the steps taken by the baths management and the railway authorities to attract patients to Harrogate. On Monday next a new fast train service between London, Leeds, Harrogate, and Newcastle will be instituted. These trains, which are made up of specially built Pullman cars, first and third classes, J. BRITISH MEDICAL JOURNAL, July 12th, 1923 (p. 15).

are timed to cover the 203½ miles from King's Cross to Harrogate in exactly four hours. Each day during the season one of these most luxurious trains will leave London at 11.15 a.m., and another travelling in the opposite direction will leave Harrogate at the same time. A trial run, organized by the London and North-Eastern Railway Company and the Pullman Car Company, in association with the Harrogate Corporation, took place last week-end. The guests on the inaugural trip included representatives of the medical press and some twenty practising medical men, mainly from the metropolis. Entertainment on arrival at Harrogate was provided at the Hotel Majestic, where a banquet to celebrate the occasion was held on Saturday evening. The health of the guests, proposed by Sir Ernest Bain, chairman of the Wells and Baths and Publicity Committee, was responded to on behalf of the medical visitors by Dr. Fortescue Fox, and on behalf of the Harrogate Medical Society by Dr. David Brown, who drew attention to the work of the Royal Bath Hospital, a local charity, which celebrates its centenary next year. This institution of 150 beds extends the benefits of Harrogate baths and mineral waters to poor patients; it had been visited during the afternoon by a number of the medical guests, who examined the wards, the reorganized bath-house, and the laboratories. Dr. David Brown mentioned, as an indication of recent progress at the great Yorkshire spa, the winter classes held during the last two years by members of the local medical society for the training of bath attendants in the rudiments of anatomy, physiology, and electricity, and in the technical methods employed at the Royal Baths. These were inspected at leisure by the visiting party on Sunday morning. In various other ways the Harrogate bathing establishment has moved with the times, and, assuming support from the medical profession, the new Pullman car train service should deflect a considerable proportion of invalids from the Continental health resorts.

#### THE INTERNATIONAL SURGICAL CONGRESS.

THE sixth congress of the Société Internationale de Chirurgie will (as already announced) be held in London from July 17th to 20th under the presidency of Sir William MacEwen. On Tuesday, July 17th, at 11 a.m. the congress will be opened by the Prince of Wales in the presence of the Foreign Secretary, the Minister of Health, and the President of the Board of Education. Many ambassadors and ministers will attend the opening ceremony, which will take place in the rooms of the Royal Society of Medicine. In the afternoon a discussion on the surgery of the endocrine glands (thyroid excluded) will be held. It may be of interest to describe how the discussions of the congress are arranged. Official reporters have been appointed, who will give abstracts of papers which have already been circulated in full. These abstracts may take not more than fifteen minutes. Then may speak for ten minutes those who have signified their desire to do so, and last, if there is time, any member of the congress may enter the discussion for not more than five minutes. The official reporters for 1923 are Drs. Bazy (Paris), MacAusland (Boston), Frazier (Philadelphia), Sauty (Lyons), Fraser (Edinburgh), Gosset (Paris), Sargent (London), Vergo (Pavia), Hey Groves (Bristol), Quénu, Duval, Moquet (Paris), Crile (Cleveland), Almoth Wright (London), Willems (Liège), Bristow (London), Platt (Manchester), Henrikson (Skien), and Putti (Bologna). On the morning of July 18th there will be a discussion on arthroplasty; in the afternoon operations will be watched at the hospitals. The proceedings on July 19th will open with a discussion on the late results of peripheral nerve injuries, to be followed by the general meeting, and in the afternoon operations will be seen. On the morning of

July 20th there is to be a discussion on vaccino- and sero-therapy (tetanus excluded), and on operative shock; after lunch, besides a programme of operations to be watched, there will be a demonstration on vaccino-therapy by Sir Almoth Wright at St. Mary's Hospital. All these meetings will be held at the Royal Society of Medicine. Entertainments have not been forgotten. The Ladies' Committee has organized visits to various places of interest in London, and an excursion to Hampton Court Palace and to Windsor. On Monday evening, July 16th, there will be a reception by the University of London. On the afternoon of July 17th Sir John and Lady Bland-Sutton will hold a reception, and in the evening delegates, members of congress, and friends will be received by the President, Sir William MacEwen. On July 18th the Lord Mayor will give an evening reception at the Mansion House. On Thursday, July 19th, there are to be receptions by the President of the Royal College of Physicians and by the President of the Royal College of Surgeons at 4 and 9 p.m. respectively. On Friday, July 20th, there is the annual banquet of the society. After these somewhat strenuous four days the visitors will probably enjoy one of the two three-day tours which have been arranged. Each begins on July 21st. One is to the Shakespeare country and Oxford, the other to Bournemouth, the New Forest, Salisbury, Winchester, and Stonehenge. The Council of the British Medical Association has offered members the use of its Library and the services of its officials. The following are amongst the many distinguished surgeons attending the congress: Drs. Hartman, Martell, Lariche, Tuffier, Røvsing, Depage, Lamotte, Willems, Schoemaker, Giordano, Putti, Soublotitch, Denègri, Bartos, Jonesco, De Quervain, W. W. Keen (who comes the doyen of American surgeons, president of the congress last year, a young man of 86), Lovett, and Matas. An interesting and novel badge has been found in a small medal bearing the figure of John of Arderne taken from a fifteenth-century manuscript. The British secretaries are Sir D'Arcy Power and Mr. J. E. H. Roberts. The offices of the secretariat are at 26, Harley Street, W.1.

THE gold medal of the Royal Society of Medicine, which is presented triennially to a scientist, man or woman, who has made valuable contributions to the science and art of medicine, has this year been awarded by the Council to Dr. F. Gowland Hopkins, F.R.C.P., F.R.S., Professor of Biochemistry in the University of Cambridge.

THE Prince of Wales has accepted the invitation of the President and Council of the Royal Society of Medicine to be present at the Society's dinner on Tuesday, December 11th.

PROFESSOR PITRES, the well known neurologist and former dean of the Bordeaux Faculty of Medicine, has been elected a member of the Académie des Sciences Morales et Politiques.

THE chairman of the London County Council is making an appeal for support for the Children's Country Holidays Fund, which enables London elementary school children to benefit both physically and mentally by a fortnight's holiday in the country. This year, owing to the financial position of the fund, it has unfortunately been necessary to estimate for about 4,000 fewer children than were sent away last year. Donations should be sent to the secretary of the fund at 18, Buckingham Street, Strand, W.C.2.

OWING to the death of Dr. H. C. Ernst the *Journal of Medical Research* has become the property of the American Association of Pathologists and Bacteriologists. It will be devoted to the publication of original observations and investigations in pathology. The price is 5 dollars net for each volume in the United States, 5½ dollars net in Canada, 6 dollars net in other countries. The editor-in-chief is Dr. F. B. Mallory, Boston City Hospital, Boston, Mass., U.S.A., to whom all communications should be addressed.

THE BRITISH MEDICAL ASSOCIATION'S NEW HOUSE.  
View of main quadrangle as it exists at present.

## NEW HEADQUARTERS BUILDING FOR THE ASSOCIATION.

The Finance Committee, after long consideration and consultation with various experts, resolved unanimously to instruct the Treasurer to accept an offer by the Disposal Board of the lease of the college for 200 years from March 25th, 1920, and to continue negotiations with the trustees of the Bedford Estate concerning certain complementary ground, with a view to obtaining possession of the frontage of about 140 feet to Tavistock Square and Upper Woburn Place.

The meeting of the Council on June 15th was interrupted in order that the members in a body should inspect the building. On the resumption of business the Chairman of Council gave a brief account of the many inquiries that had been made with regard to various sites, and showed plans of the site now selected and of the college building upon it. He pointed out the advantageous position of the site abutting upon one of the chief north and south thoroughfares in London, in close proximity to the chief railway termini from the North (King's Cross, St. Pancras, and Euston), and lying practically equidistant from the Underground Stations at Euston Square, King's Cross, and Russell Square. He said that at 429, Strand, the Association had accommodation represented by just under 18,000 square feet of floor space. It was estimated that any new premises ought to have a total of 42,000 square feet. Both these figures excluded the space required for corridors, entrance, lift, etc., and the estimated requirements included provision for a large conference room, and for the proper housing of the library, as well as for adequate Council and committee rooms. The building which the Council had just inspected had a total floor area of 58,000 square feet, including passages, lavatories, and so forth. Standing on an ample site, the provision of full social facilities for members in the way of meeting rooms, and even all the amenities of a club, were within its scope.

The house of the British Medical Association (429, Strand) has for some years proved increasingly inadequate for the growing activities of its departments, and accommodation originally intended for the use of members generally has been gradually absorbed for business purposes. The position has been under consideration for some time, and the Council, at its meeting on April 18th last, adopted a resolution to the effect that the time had arrived when steps should be taken towards securing a British Medical Association building or site not only adequate for likely future office requirements, but also capable of providing small and large hall accommodation. The Council on the same occasion authorized the Office Committee to take steps towards obtaining increased accommodation and gave it power to enter into negotiations, including the taking of an option, if necessary. The Office Committee referred the matter to a subcommittee, consisting of the officers of the Association (the Chairman of Representative Meetings, the Treasurer, and the Chairman of Council). At the Council Meeting on June 15th the subcommittee was able to report that it had examined a large number of sites, and had come to the conclusion that the most suitable course was to enter into negotiations for a site on the Duke of Bedford's Estate in Bloomsbury. There was already upon it an imposing building, designed by Sir Edwin Lutyens, R.A., for the Theosophical Society; this building had been completed up to a certain point when it was taken over by the Government. It was used by the War Office during the war as the London Command Paymaster's Office. Afterwards it was handed over to the Disposal Board.

The modern demand for garage accommodation could readily be met within the precincts of the building.

The Treasurer reviewed the financial aspects of the proposed transaction, and concluded by saying that the whole matter came practically to this: That the Association, in removing from the one building to the other, must face the higher maintenance cost of the increased accommodation. The chief assets of the Association were the present valuable freehold building in the Strand and the reserve fund. He was satisfied that the purchase contemplated was an advantageous transaction for the Association, and that the financial position was such that the Council might unhesitatingly approve the project. After some further discussion, Dr. John Stevens moved the formal approval of the recommendation; this was seconded by Dr. Ridley Bailey and supported by Dr. Crawford Treasure, Dr. Radcliffe, Dr. Darling, Colonel C. B. Heald, Dr. C. E. Douglas, and Mr. McAdam Eccles. The Chairman then put the resolution sanctioning the proposal, and it was carried without dissent amid much applause.

We reproduce on the preceding page a photograph of the main quadrangle, or courtyard, facing the north-east corner of Tavistock Square, as it appears to-day in its unfinished condition. It will, perhaps, serve to give members of the Association some idea of the general proportions of the building. When completed the new house of the British Medical Association will, we venture to say, be regarded as the handsomest structure of its kind in modern London, and a worthy memorial to the genius of its architect. It is built of red brick, with white stone facings. The centre archway is at present filled in temporarily with rough brickwork, which, together with other makeshifts, will be removed during the process of fitting the building for its new purpose. This it is hoped to carry out under the advice of Sir Edwin Lutyens.

### GOLF COMPETITIONS AT THE ANNUAL MEETING.

The British Medical Association holds each year a golf competition wherever the Association happens to be holding its annual meeting. In the past members have only had the privilege of playing for one cup—namely, the Ulster cup, presented to the Association by the Ulster Branch, and first played for during the annual meeting at Belfast in 1909. This year, by the kindness of the President-elect, who has presented the Childe cup, members will compete for two cups. Both will be played for during the same round. The Ulster cup is open to all members of the Association, the maximum handicap allowed being 18; the Childe cup is open to all members of the Association who have a handicap of 10 or over, 18 being the maximum again allowed. Play in both cases is against bogey. If the Ulster cup is won by any competitor with a handicap of 10 or over, the Childe cup will be presented to the player (with a handicap of 10 or over) with the next lowest score. The Portsmouth Division has kindly offered to present small memento cups to the winners of both the Ulster and the Childe cups.

Conditions of play are as follows:

1. One round of 18 holes to be played on Thursday, July 26th, by kind invitation of the Hayling Golf Club at their course on Hayling Island.
2. Competitors are not permitted to put in previous play on the course on the day of the competition.
3. Intending competitors are required to furnish with their entry a certificate signed by their club secretary stating (a) their lowest handicap, (b) the bogey score of their own course, and (c) the length of their own course.
4. Entries to be made at the Reception Room before 4 p.m. on Wednesday, July 25th.
5. Competitors may choose their own partners, although partners will be arranged for by the committee on notice being given at the time of entry.
6. Play to commence at 10 a.m., no cards to be issued after 3.30 p.m.

It is hoped that all members who attend the Annual Meeting and who play golf will enter for these competitions. Lunch will be served at the club house, and by kind invitation the competitors will be entertained at tea in the afternoon.

### CANADIAN MEDICAL ASSOCIATION.

THE fifty-fourth annual meeting of the Canadian Medical Association, held in Montreal on June 12th and three following days, was largely attended, more than 800 members and guests being present. A number of other medical organizations held their annual meetings at the same time; these included the Canadian Society of Anaesthetists, the Canadian Radiological Society, the Canadian Society for the Study of Diseases in Children, the Canadian Medical Protective Association, and the Province of Quebec Medical Association.

In his address of welcome Sir Arthur Currie, Principal of McGill University, said that Montreal was fast becoming a Mecca of conventions, but no convention that had been welcomed here had brought more honour to the city than that of the Canadian Medical Association, whose members came not particularly for their own pleasure or advancement, but chiefly that the community might benefit. Referring briefly to the aims and ideals of the profession and to the value of such an organization as the Canadian Medical Association, the Principal expressed the hope that the general public and the Government, Dominion and Provincial, would take a more active interest in medical advancement.

### THE WORK, PRESENT AND FUTURE, OF THE CANADIAN MEDICAL ASSOCIATION.

Dr. Malcolm MacEachran of Ottawa gave an address on what the Canadian Medical Association stands for. There were, he said, eleven hundred doctors in actual practice in Canada; this was an average of one doctor to every 862 inhabitants, but the distribution was not even. He gave an outline of the organization and aims of the Canadian Medical Association, and mentioned its desire to possess national headquarters. He spoke also on the problems of hospitalization, transportation of the sick, medical education, training of interns, and the better correlation of preventive and curative medicine.

It was arranged for lecturers to visit various provincial centres to speak on the most recent developments of medicine and surgery. The three lecturers appointed were Dr. F. W. Marlowe of Toronto, Dr. F. J. Tees of Montreal, and Dr. T. C. Routley, Secretary of the Association. It is planned to start at Victoria, B.C. on July 3rd. The centres visited will be Vancouver, Edmonton, Calgary, Saskatoon, and possibly Moose Jaw and Winnipeg. Drs. Marlowe and Tees will give scientific addresses and Dr. Routley will speak on organization work. Three representative committees were appointed to study questions relating to medical education and legislation. It was suggested that a medical conference be held some time during the coming winter with a view to bringing together all bodies in Canada interested in such matters.

The distribution of the doctors throughout the country is a vexing question. Some districts are almost totally without medical aid, whilst in other parts of the country the supply exceeds the demand. It is hoped that the association will take up the matter seriously and suggest a remedy to relieve the situation.

Men without medical qualifications are presuming to practise medicine in the west, and this usurpation of privileges is spreading to the east, to the general lowering of the standards of the profession. The Hon. J. D. McLea, M.D., Provincial Secretary and Minister of Education and Railways, British Columbia, told the members of the Canadian Medical Association that there was need for strenuous fighting to eliminate this scourge of the profession. "One difficulty we have in our province," he said, "and one that you will have in the eastern provinces in times to come, are the followers of many cults who are presuming to practise medicine. There are some men practising medicine to-day who are not as well educated along medical lines on which they are practising as they ought to be. Precautions must be taken and some methods adopted whereby these men shall be brought to a higher standard of efficiency. It is a question that men will have to face in eastern Canada as we are facing it now in the west and in the Western States of the

United States. Judging by my observations, there is one thing the medical profession must do: there must be to some extent a house-cleaning."

Following Dr. McCann, Dr. R. W. Powell of Ottawa, president of the Canadian Medical Protective Association, referred to actions taken by the Protective Association for malpractice, negligence, or want of skill. "As we go on," he said, "the greater we see the value of organized defence, of straightforward fighting, of no compromise."

In submitting the report of the general council of the Protective Association Dr. J. R. Kenton argued expressed the belief that the limiting of the association work to its members had brought matters to a pass where a change of policy had become necessary. On the motion of Dr. W. G. Reilly a resolution was passed unanimously calling upon the executives of the Medical Association and the Protective Association to confer, in the hope of evolving a scheme by which membership in the former association would carry with it the protection afforded by the latter association.

The affiliation of the Medical Association of the Province of Quebec with the Canadian Medical Association was confirmed, which means that all of the nine provincial associations are now linked up under the Dominion organization. The making of the Canadian Radiological Society a branch of the Canadian Medical Association was also approved. The members decided to petition the Dominion Government to increase for income-tax purposes the deductible sum for dependent children to 500 dollars. It was decided to hold the next annual meeting (1924) in Ottawa. The following officers were elected for the ensuing year: Dr. John F. Kidd of Ottawa was named president; Dr. A. D. Blackader was elected editor of the *Journal*; Dr. A. T. Bazin was made honorary treasurer, and Dr. T. C. Rountley of Toronto general secretary.

#### CHEMICAL AND SCIENTIFIC PROCEEDINGS.

The clinical and scientific work of the meeting was carried out in sections, including pathology, dietetics, diseases of the ear, nose, and throat, and radiology, and at general meetings. At one of these Dr. S. A. Knicker Wilson gave a history of the National Hospital for the Paralyzed and Epileptic in Queen Square, London, sketched the work of the men that made it, and described its organization.

A discussion on infection of the hand was very largely attended. The chief speakers were Mr. I. MacLaren Thompson, Department of Anatomy, McGill University, who dealt with the anatomical structure of the hand, Dr. W. A. Ferguson spoke on the development of treatment in infections, showing the advance made in scientific management of traumatic injuries. Dr. D. D. MacLagarty, Professor of Medical Jurisprudence, McGill University, dealt more particularly with disabilities of the hand in their economic relationship.

Dr. William J. Mayo (Rochester, Minnesota) gave an address on the septic factors in tuberculosis, syphilis, and carcinoma; with regard to the latter he said:

"Glandular involvement in carcinoma tells the story. While operative skill and technique are important, generally speaking, results show that, although regard to the type of operation, the year curves occur in 71 per cent. of cases in which an operation has been performed for carcinoma before the glands are involved, and in only 19 per cent. after they are involved. Local operations cure local disease; massive operations fail when the local stage has passed. The associated sepsis in cancer is the cause of much of the distress, and hurries the patient to a fatal end. We all recognize the dangers of operation on the infected, so-called inflammation in these cases, followed later by plastic repair, is a step in the right direction. There are many men who, with a small amount of radium, do little good and an enormous amount of harm. With good faith, but poor judgement, they apply radium in cases in which an operation should have been performed early. Generally speaking, the use of radium means the parting of the ways. If radium is selected, one can seldom turn back and take the operative route with a good prospect of success."

Sir William Taylor (Dublin) followed with an address on intestinal obstruction.

Dr. Luther C. Peter of Philadelphia was the first speaker in a discussion on the diagnostic value of modern perimetry in diseases of the visual pathway, and Dr. W. G. M. Byers of Montreal spoke on the treatment of tuberculosis of the

eye. The surgery of the mastoid was dealt with by Dr. Edmund Boyd of Toronto; and unusual findings, with pathologic specimens, in the neuro-otological examination in a verified brain tumour in a child was discussed by Dr. D. E. Staunton Wishart, also of Toronto.

A discussion on insulin and diabetes was opened by Dr. F. C. Banting of Toronto, and it was subsequently announced that the Federal Government would be asked to recognize suitably the work of Dr. Banting and his collaborators, including Dr. C. Best, and that some special recognition should be given also to Professor Macleod, in whose laboratory in Toronto the work was done, and to Professor Collip.\*

Dr. J. S. Fraser, surgeon to the Earl, Throat, and Nose Department of the Royal Infirmary, Edinburgh, gave an address on diseases of the ear. Sir Robert Jones gave a demonstration on orthopaedic surgery, in the course of which he discussed several series of cases of surgical tuberculosis, club-foot, and other deformities, which had been collected for him, and indicated the treatment he recommended in each. The demonstration was attended by over 500 members, who, at the conclusion, expressed their appreciation of the demonstrator's efforts.

The Canadian and the British Medical Associations proposed that an invitation should be given to the British Medical Association to visit Canada so that a joint meeting of the two associations might be held. In placing the matter before the meeting Dr. C. F. Martin, President of the Canadian Medical Association, said that a set of questions had been sent out to members asking whether they approved such an invitation. Of the replies received 1,223 were in the affirmative and only 28 in the negative. This statement was received with cheers, and the proposal was unanimously approved.

Dr. C. F. Martin afterwards presided at a luncheon given to Lord Sharncliffe and Sir Robert Jones. More than 300 members of the Canadian Medical Association were present. Afterwards Sir Robert Jones gave a short address on the imperial relationships of medicine. In the course of his remarks, he said:

"I cannot imagine any theme more likely to prove the next science. I also cannot picture any subject that would respond to the hopes and aspirations of us all more deeply. But it is to emphasize an aspect that possesses immediate importance. First of all, what is meant by imperialism? There is no denying that, before the great war made the word synonymous with contempt, there was a certain antipathy and suspicion towards the very name, principally founded upon a false conception of dependence. The war, out of its long agony and affliction, produced one progressive and not simply destructive achievement—it cemented imperial relationships. It was in that sense a challenge. It proved as never before that dependence one upon another in a common cause is a greater and more progressive ideal than isolation. It proved in our particular civilization the profound possibilities of team work; it taught us all the lessons, in other words, of unity of effort founded, not upon jealousies, water-tight compartments, or indifference, but upon comradeship and high ideals. The war has gone, and with it much of its dramatic and urgent challenge. But in its place is the infinitely more permanent challenge of peace. Is all that enthusiasm, fraternalism, and unbounded promise to cooperate and pass into a tepid tolerance? Does it require the stringency and destruction of war to make an ideal common to us all more than an individual occupation? Surely not. Without question every effort should be made to maintain our past and present relationships."

"Consider under such an idea—so reasonable and so inevitable—the prospect of a closer alliance between the British and Canadian fields of medicine. I admit that on the grounds of sentiment alone the promise of such co-operation possesses a peculiar and lofty idealism. The tie between the medical traditions of your land and the land of your fathers results there any need for me to remind you how deeply the professions in Great Britain respect you and how concerned they are for the greatest possible unity with you. I was asked to make the point as clear and to emphasize it as strongly as I am able. It is now reported that the Ottawa Parliament has voted Dr. Banting an annuity of 1,500 dollars."

It is now reported that the Ottawa Parliament has voted Dr. Banting an annuity of 1,500 dollars.

It is now reported that the Ottawa Parliament has voted Dr. Banting an annuity of 1,500 dollars.

able, and I do so now more gladly than I can say and less eloquently than I wish. There is, I know, nothing but goodwill on your side; it has been shown too plainly for misconstruction.

"Certain conclusions occur to me as an outsider. I am not here to formulate machinery for closer co-operation, for the simple reason that if the determination and goodwill are there, such technicalities come within the work of the committees concerned. All that can be emphasized, as I trust it will by our friends on this side, is the realization that progress is won not so much by independence as dependence one upon another. There is no question of interference with your autonomy or ours, any more than with our colleagues in Australia, New Zealand, or Africa. Out of such an alliance, who can tell what may not come in the future? but it is enough for us that our ideal should be that of a large family distributed, as is the way with large families, throughout the world, each master in his own house, but each with a sense of more than goodwill concerning the other habitations, and even a kind of family pride in their success and a loyal fellowship in their troubles."

The cablegram sent on behalf of the Council of the British Medical Association, as stated in a Current Note published last week, was read and very cordially received by the company. The letter addressed to the President of the Canadian Medical Association by the Chairman of the Council, confirming the invitation, will also be found in the SUPPLEMENT of last week.

### MEDICAL PRACTICE IN THE SCOTTISH HIGHLANDS.

THE most interesting part of the newly issued fourth Annual Report of the Scottish Board of Health<sup>1</sup> relates to the work of the practitioners under the Highlands and Islands (Medical Service) Grant Act, 1913. The Board states that there are signs that medical practice in the Highlands and Islands is growing increasingly attractive to doctors. For posts recently advertised there have been unexpectedly numerous applicants, and those who had left the area show an inclination to return. The report goes on to say that, apart from improved finance, the increasing popularity of the service is believed to be due, at least in part, to the sympathetic attitude of the British Medical Association and of its Highlands and Islands Subcommittee. Also, of the more recently qualified doctors who have been employed in emergency and holiday service in the Highlands, a proportion seem inclined to seek permanent posts, the temporary work having been to their liking. The result is that the service is now practically at full strength except in a few districts of exceptional difficulty owing to lack of suitable houses, or other reasons. For example, in the Island of Lewis one district of 354 square miles with 11,000 population has only two doctors, on account of want of houses; in another area it is very difficult to get a building site sufficiently level and free from rocks, while the hunger for arable land creates objection to giving up a feasible patch large enough to hold a house.

Special financial arrangements have had to be made for some isolated communities too small to occupy the full time of a doctor. Among the examples given of the difficulties encountered, that of Fair Isle, situated midway between the Orkney and Shetland groups, may be quoted. Down to the end of 1922 each visit to the island meant 150 miles of sea travel; a new arrangement for attendance from the south of Shetland is better, but it will require 50 miles by sea for each visit, or 100 miles if the boatman has to come from the island; the crossing includes Sumburgh Roost, where the troubled sea is kept in constant turmoil by the meeting of two tides. Such island work indeed is largely at the mercy of storms and fogs. On the Fair Isle a medical officer was recently fogbound for a week, and on the remote island of Foula another was detained for four days last July. Here is a striking account of a case in which, notwithstanding every effort, the weather rendered it impossible for a medical officer in Portree (the capital of Skye) to make a visit to a patient in the Island of Soay, to the south of Skye:

"I received a telegram from Elgol on Friday morning asking me to go to a man (on the Island of Soay) who had

damaged his eye. . . . I had several patients in at the time who had come from North Raasay to consult me, and they kept me until about 12 o'clock noon. I then set out for Soay, but had to see an important case in Portree before going. . . . On the road to Glenbrittle, the last eight miles of which is very rough, I had considerable tyre trouble involving a good deal of delay, so that I did not reach Glenbrittle until about 4.30 p.m., when it was beginning to get dark. On finding that the boat from Soay was not at Glenbrittle to meet me I went to the guide at Glenbrittle and asked him to guide me across the hill—a distance of about three miles—to the place from which one can signal (by lighting a fire) to Soay for a boat. The guide refused to undertake the journey in darkness on account of the dangers. I may say that there is no track, and that there are three streams to cross, over which there are no bridges. I waited all night at Glenbrittle. During the night and in the morning heavy rain fell and a strong wind was blowing. When we again set out we found that the streams were quite impassable, and I then decided to try to cross from Elgol. I came back to Sligachan, and from there wired to Elgol asking if I could get across to Soay from there. While waiting for the reply I had again to change my tyres, borrowing one from a passing car. I received a reply from Elgol that it was impossible to cross to Soay that day."

The fund provided by the Act has been applied to medical service, nursing service, houses for doctors and nurses, hospitals and ambulance service, telegraphs and telephones, a special emergency scheme, and a special tuberculosis scheme.

The object of the medical service, it may be recalled, is to secure that distance of doctor from patient shall not add anything to the charges to be paid by the patient; small fixed fees, no matter what the distance is, are paid for first visits and for subsequent visits, and the doctor is subsidized from the fund to meet the deficit, usually by an annual grant, but in a few cases by a guaranteed income. The payments to doctors are under three heads, and for 1922 the amounts were estimated as follows: (1) Scheme of modified fees and special arrangements, £44,000; (2) supplementary scheme (mileage) £1,120; (3) holiday relief, £855.

It is to be understood that the Highlands Act is not in substitution for the Insurance Act, but in supplement. The Act owed its inception to the Scottish Insurance Commissioners, who, after their appointment, speedily realized that the Insurance Act fell far short of meeting the case of the Highlands, where the chief occupations—especially fishing and crofting—are not carried on under any contract of service. The Commissioners accordingly made a representation to Government, and a committee of inquiry was appointed; its report was followed by the passing of the Act. Last year the nursing service was expected to cost £8,500, houses for doctors and nurses £3,199, and hospitals and ambulance service £700. The annual grant is only £42,000, but owing to the war some of the contemplated services remained largely in abeyance, so that the fund rapidly increased. At the beginning of last year it was £172,624, but by the end of the year it had fallen to £143,459. In a very few years, therefore, Parliament will be faced by the fact that the funds will not nearly meet the outlay. Indeed, the expenditure in 1922 considerably exceeded the estimates above mentioned, medical services having cost £63,798, and nursing services £10,206. But of the benefit to the population of the Highlands and Islands there can be no doubt whatever.

As pointed out in an article on "The country practitioner" (May 26th, p. 904), the Highlands Fund is not the only subsidy outside the Insurance Act to medical service in Scotland. For specially difficult and remote parts of what are technically the Lowlands—parts of Aberdeen, Banff, Dumfries, etc.—there is a Necessitous Districts (Lowlands) Grant, devoted to removal to hospital, transmission of messages, establishment of doctor, subvention to income, means of conveyance, maintenance of dispensary, difficulty of access, and footpath miles. The total outlay must be quite small, but no figure is mentioned in the report. The principle, however, is of much importance—namely, that in the public interest medical and related services in sparsely populated and difficult areas may be specially assisted by grants voted by Parliament and administered by the central health authorities.

In a later article we hope to refer to the parts of the Board's report dealing with the Insurance Act.

# Abstract Notes in Parliament.

[FROM MR. CHAMBERLAIN'S CONSPIRACY.]

## The Ministry of Health for England and Wales.

### A Year's Work.

PRACTICALLY the whole of the sitting of the House of Commons on June 23rd was taken up by a discussion on the vote for the Ministry of Health. Mr. Neville Chamberlain, in illustration of the economic importance of public health, mentioned that among the insured population in 1922 upwards of 19,500,000 weeks were lost by sickness. This was the equivalent of loss of work by 375,000 persons for a whole year. But only by adding the corresponding figures of uninsured people, whatever these might be, could be estimated the full importance of a permanent health service. An examination of vital statistics was encouraged, especially when allowance was made for the exceptional hard conditions of the last three or four years. The death rate in the first ten years of the century was 15.4 per 1,000; in the next ten it fell to 14.3; and last year to 12.8. In the five years 1910-15 the infant mortality rate was 11 per 1,000; in 1921 it was 9; in 1922 it was 8.5; and last year it was 7.7. A baby born to-day could expect to live twelve years longer than it is grandfathers could have hoped.

It was thought by many that tuberculosis and cancer were the most fatal diseases, but that was far from being true. Respiratory diseases, such as pneumonia and bronchitis, came first in fatal effects. This high mortality was to be attributed to the congested conditions and polluted atmosphere of the large towns. After a thick fog the death rate in London went up. He hoped that before very long he would be able to introduce legislation to help the campaign for cleansing the atmosphere. Next in fatal effects were diseases affecting the heart, and third came those of the nervous system.

Cancer, which now caused 96 per 1,000 of all the deaths from all causes, was fourth, and there was no doubt, unappreciated, that deaths from this disease were increasing. In 1900 the rate per million of the population was 82; ten years later it was 96, and in 1921 it was 125. The figures were very different despite allowance for better diagnosis and the fact that more people reached the span called the cancer age. The Ministry of Health had a standing Medical Committee on cancer, and researches were being carried on by the Cancer Research Fund, Middlesex Hospital, and the Cancer Hospital, Fulham Road. In addition, the subject was under the constant attention of the Medical Research Council, and there had lately been started another body—the British Empire Cancer Campaign. If this organization could succeed in co-ordinating with the existing bodies and form some co-ordinating influence, he would heartily welcome its existence and be glad to give it his support.

The position with regard to tuberculosis was more concerning. The death rate per million last year was only 85 as compared with 2,653 in 1867. With regard to smallpox, the death rate per million last year was only 85 as compared with 2,653 in 1867. With regard to smallpox, the death rate per million last year was only 85 as compared with 2,653 in 1867. With regard to smallpox, the death rate per million last year was only 85 as compared with 2,653 in 1867.

Mr. Chamberlain afterwards referred to the fact that the death rate per million last year was only 85 as compared with 2,653 in 1867. With regard to smallpox, the death rate per million last year was only 85 as compared with 2,653 in 1867. With regard to smallpox, the death rate per million last year was only 85 as compared with 2,653 in 1867.

Mr. Chamberlain said that the death rate per million last year was only 85 as compared with 2,653 in 1867. With regard to smallpox, the death rate per million last year was only 85 as compared with 2,653 in 1867. With regard to smallpox, the death rate per million last year was only 85 as compared with 2,653 in 1867.

done by them in the vast majority of cases was extremely good. The support given to cancer research was inadequate. To be efficient it must have the support, supervision, and sympathy of the Ministry of Health.

Lord E. Percy, on behalf of the Ministry of Health, said he thought it was obvious that the Government must give adequate assistance to the work of cancer research. Dealing with criticisms of certain reductions of expenditure, he said that for tuberculosis work it was about 3 per cent., but prices and cost of administration had gone down more; the actual service had expanded. The reduction in the amount for maternity and child welfare was about 15 per cent., but he believed that there also the cost of administration had gone down more than the reduction in the estimate. The service was to be as efficient and widespread as last year.

After reference by several Labour members to the effect of crowding on the spread of tuberculosis, Mr. Falconer, a Scottish Liberal, offered some criticism of panel doctors, while agreeing that the majority recognized their obligations. Sir Walter Preston feared that proper steps were not being taken to deal with the outbreak of small-pox in Gloucester, and gave his reasons at some length. Mr. Clynes summed up the debate on behalf of the Labour party, and incidentally returned to a charge made by Mr. Lansbury that under recent restrictions no child over 12 months got milk. Lord E. Percy, interposing, read the terms of the circular issued as long ago as March 31st, 1921, under which milk may be supplied to children up to 3 years of age, and exceptionally to children between 3 and 5 years of age.

Mr. Chamberlain agreed with Sir Alfred Mond that the panel system, whatever might have been its defects and faults, had done very valuable service by raising the standard of medical attendance among the poorer classes, but he did not question that it could be improved. Since 1920 much had been done to strengthen the weak places and to correct some of the faults disclosed in the course of experience. An attempt had been made to obtain a ubiquitous service, so that any insured person wherever he was might always be able to obtain the services of a panel practitioner; that was secured by a system of remuneration not dependent on the payment of a fixed sum per person. An endeavour had been made also to secure that patients should not be charged for any services properly within the scope of the service, and that the accommodation of the surgeries should be adequate and sufficient; it was one of the matters it was hoped to improve in the course of the next year. Mr. Chamberlain also referred to the appointment of regional medical officers to act as consultants. With regard to new terms to apply when the present terms of remuneration came to an end in 1924, the Ministry of Health had had a number of discussions already on such subjects as the limitation of a panel; that there should be no private fee for services within the scope of the contract; that there should be greater freedom in the choice of doctor; and that the Ministry should be able to secure that proper records were kept of each case. When agreement was reached on various points the Ministry would have to go into the question of remuneration. This matter would be discussed in the House sooner or later, very probably in the course of the autumn session, because it was most likely that further legislation would be necessary to put into operation the new arrangement. It would be unfortunate if the announcement of the coming of any thorough drastic inquiry in the whole system were to postpone the settlement of various questions he had mentioned or delay the settlement coming into operation. It would be necessary at some time or other to have an inquiry such as Sir Alfred Mond had suggested, but being desirous of a speedy settlement he did not think that time had arrived.

As to the Spahlinger treatment, he was told that a movement was going on to raise a sum of money privately which if successful—as he had some reason to hope it might be—would enable Mr. Spahlinger to produce his remedies in sufficient quantity to be available for experiment, and he would send a supply of these materials over here, where they would be handed over to the Ministry for complete examination. Dr. Dreyer's method, as to which very much more complete information was available, was extremely encouraging. No kind of remedy which offered a reasonable chance of success should be neglected.

Replying to inquiries about the grading of milk, Mr. Chamberlain said he had not yet got returns from the local authorities enabling him to give figures, but he had every reason to believe that the matter was proceeding satisfactorily.

The vote was agreed to.

#### Scottish Board of Health.

On a vote for £1,773,730 for the Scottish Board of Health, to follow a vote of £720,000 already given on account, Captain Elliot, on June 27th, made the annual review of administration. He went with some detail into statistics of tuberculosis, infant mortality, and health insurance to ascertain how far trade depression had affected health. The average death rate from tuberculosis (all forms) in 1910-14 was 172 per 100,000; in 1921 it dropped to 118; and in 1922 it was 119. For England and Wales, for the corresponding period, the rates were 140, 113, and 112. From phthisis the average death rate for 1910-14 was 111, and in England and Wales 102. In 1921 the rate was 81 in Scotland and 83 in England and Wales. In 1922 the rate in Scotland had increased to 83 and for England and Wales to 89. It was most encouraging that, speaking broadly, the lower death rate had been maintained in spite of the great trade depression. In 1913 the rate in Budapest was 611; in Warsaw 591, in Lodz 775, in

Jugo-Slavia 400 to 500, and in Czecho-Slovakia 386, as compared with 160 in Scotland and 169 in England and Wales. Captain Elliot then gave a number of comparative figures as to infant mortality. The suggestion had been made that the limitation of grants for child welfare had brought about an increased death rate. In point of fact the rate had fallen. The rate per 1,000 births for 1870-80 was, in Scotland 123 and in England and Wales 149. For the period 1911-15 the figures were 113 for the former and 110 for the latter. In 1920-21-22 the figures for Scotland were respectively 92, 90, 101, and for England and Wales, 80, 83, and 77. In the first quarter of last year the rate was 141 for Scotland. That was when maternity, milk, and food grants were given. In the corresponding quarter of this year the figure was 98. It was true that epidemics of measles and influenza had much to do with this high rate, but the fact remained that the figures were higher in the quarter while the grants operated than in the three quarters when they did not. The policy of dissociating maternal care and child welfare from relief agency work had not been seriously challenged by any responsible authority. As regards health insurance, Captain Elliot said that the expenditure per week per insured person was 2d. in 1913 and 2½d. in 1914; the expenditure for males on sickness benefits was less than 2½d. in 1920 and less than 2½d. in 1921. It was an increase, but balanced by a big increase in the percentage of benefits. The Ministry had been able to pay 50 per cent. of the grant for tuberculosis to the local authorities as promised. The average weekly cost for institutional maintenance in all Scotland, excluding loan charges, was 49s. The estimated cost of the middle ward in Glasgow was 71s. a week. The figures for Glasgow for tuberculous patients treated in fever hospitals was 57s. per week, and the corresponding Mid-Lanark rate was 46s., as compared with the Edinburgh figure of 37s., the Dundee figure of 36s., and Aberdeen 38s. Some further scrutiny of these figures was needed. Captain Elliot said there had been interesting conferences on venereal diseases with the local authorities which are dealing with venereal diseases. There was a widespread feeling that further powers of compulsion should be given to the authorities. Compulsory notification and compulsory treatment were both urged, but the subject involved questions beyond his immediate scope. It was hoped that a report of the death rate amongst mothers, prepared by a strongly representative committee, would soon be available.

Mr. Sullivan moved a reduction of the vote by £10, mainly to condemn the lessening of the welfare grant.

Dr. Chapple rejoiced that, despite unemployment, the mortality from tuberculosis had been going down. He also thought that the figures as to infant mortality for the last ten years were satisfactory. He deplored, however, that the local authorities were continually confronted with the problem of waiting lists for the sanatoriums. These institutions had two functions—curative or for isolation. And he deeply regretted that people should be left in the last stages in the slums of the great cities, where families lived together and where so much harm might occur through infection. He appealed to the Government to spare nothing to remove the causal conditions of disease that existed to-day.

Mr. Maxton, on behalf of the Labour party, spoke bitterly of the higher rates for tuberculosis in Scotland as compared with England. He then referred to the decision that the arrangements for emergency supplies of food and milk to nursing mothers and infants on a large scale must be regarded simply as measures for the relief of distress and withdrawn from association with maternity service and child welfare schemes. He went over the statistics of infant mortality to show that, in consequence of the change, there had been an increase in the death rate from 90.3 to 101.4 per 1,000.

Captain Elliot, interposing, said he had already pointed out that the majority of the deaths took place in the quarter when the policy of relief grants still operated.

Mr. Maxton, continuing, claimed to be using the figures with moderation, his point being that the Minister ought not to be satisfied with them. At the time that the epidemics of measles, influenza, and whooping-cough were raging a circular was issued by the Board saying it could no longer approve of the provision of hospital accommodation for children suffering from whooping-cough and measles. He called the men who initiated that policy murderers, and those who walked into the Lobby in support of it also murderers.

While Mr. Maxton was developing this accusation in hectic language Sir Frederick Banbury raised a point of order, and there followed a scene which has been described in the daily press. Mr. Maxton and Mr. Wheatley, in spite of appeal from the Deputy Chairman, from Mr. Bridgeman, and indirectly from their own leader, Mr. Ramsay MacDonald, persisted in repeating the unparliamentary phrase, and in the end they were reported to the Speaker and a motion for their suspension carried. Two other members, Mr. Stephen and Mr. Buchanan, were afterwards suspended for persistently disregarding the authority of the Chair.

Other Labour members afterwards pursued the debate more moderately. Mr. Macpherson, coming later, paid tribute to the services of the Board of Health in connexion with the Islands and the Highlands, and to the work done by the nursing service. He

capable and skilful surgeon, as an author, and as a successful teacher. He came of a fighting stock; several of his forebears had fought at Waterloo. He himself had first given surgical service during the South African campaign. In the recent war, both as an operator and an administrator, he had been of the greatest assistance to the army and his country. It was common knowledge that many young medical men who had gone to the front found themselves placed in circumstances where they had no opportunity of utilizing the knowledge and experience they possessed. Sir Anthony Bowlby had righted things for many of these men, and thus, in return, got out of them the best work possible. The country generally was grateful to Sir Anthony Bowlby for all that he had done. The toast was most heartily received. In his reply, Sir Anthony alluded at considerable length to his association when at the front with the Northumbrian Division. He paid a high compliment to the fighting spirit and bravery of the men of the North, particularly to what they had done on April 27th, 1915, when the enemy, near St. Julien, launched his first gas attack. He spoke of the great services rendered by the surgeons of the North of England, especially of those of Mr. John Clay. At Hazebrouck there remained the kindest of memories of the surgeons from the North of England. The excellent work done by Mr. Hamilton Drummond was specially alluded to, while to Dr. Horsley Drummond an equally well-deserved compliment was extended. Dovetailing between his serious remarks a short humorous story now and then, Sir Anthony's reply was most favourably received. To Sir Theodore Morrison was entrusted the toast of the Medical Graduates' Association. He pleaded for making the North of England a "resistance centre." There was too great a tendency to regard London as the one place where the best work of the country was done and that thither all the best brains went. He maintained that there were just as capable men in the provinces and as many of them as in the metropolis. The President, Mr. Joseph Leech, replied; after mentioning that the association was founded in 1880, he expressed the hope that more graduates would feel it their duty to become members of it. The pleasure of the evening was enhanced by music and song.

#### TREATMENT OF TUBERCULOSIS IN LONDON.

The Public Health Committee presented a report to the last meeting of the London County Council on the tuberculosis dispensary service and the work of tuberculosis care committees. At a recent conference between representatives of the Council, of the City Corporation, and of the borough councils it was resolved to draw the attention of the London Panel Committee and the British Medical Association to the desirability of securing earlier notification of cases of tuberculosis. The letter received from the County Council is printed on page 43. The borough councils which provide hospital dispensaries and the borough councils concerned in cases in which there is lack of co-ordination between the borough public health department and the municipal dispensary are to be urged to take steps to secure closer co-operation between the department and the dispensary. A proposal that facilities should be provided for the post-graduate instruction of tuberculosis officers was favourably received by the conference of local authorities, and the Public Health Committee has since been in communication with the Ministry as to the practicability of an expenditure not exceeding £1,000 for this purpose during the current financial year ranking for Government grant. The Ministry has intimated that it will be prepared to give an approval carrying a grant to satisfactory proposals from metropolitan borough councils within this limit of expenditure. The Public Health Committee is now in consultation with the Ministry of Health as to the nature of the arrangements which can best be made.

#### SMALL-POX IN GLOUCESTER.

The situation at Gloucester, where there is an outbreak of small-pox, remains serious, but it is being dealt with efficiently and firmly. Down to July 3rd, 191 cases of small-pox had been admitted to the Brockworth Isolation Hospital, near Gloucester. Dr. W. H. Davison, assistant

medical officer of health for Birmingham, has been given a free hand by the Gloucester City Council to take all measures he considers necessary. He is being assisted by two medical men with wide experience of small-pox, who have been lent by the Metropolitan Asylums Board. Some of the difficulties with which Dr. Davison has had to grapple may be realized from a report, in the *Birmingham Post* of June 28th, of a meeting of the Gloucester City Council on the previous day. It was stated that the matron of the isolation hospital had resigned and proposed to leave at once. Captain J. Wood, chairman of the Public Health Committee, in moving the adoption of the minutes, referred to an article in which Dr. Hadwen had said, "I do not believe that there is a single case of small-pox in Gloucester." The Health Committee had evidence that absolutely disproved Dr. Hadwen's statement. The article also assailed the professional qualifications of Dr. Davison, whose services had been of the greatest value. Dr. Killick Millard, medical officer of health of Leicester, had seen the cases and confirmed Dr. Davison's diagnosis of small-pox. Dr. Millard said, "Every case I have seen is a case of small-pox." Captain Wood asked him if he had seen a single case of chicken-pox in the hospital, and Dr. Millard's reply was, "No, not one; nor can I understand how any medical officer can say these are not cases of small-pox." A letter had been sent to the public vaccinator from a Gloucester father, in which he said that out of eight children in his home, two had been vaccinated, and they had not a blemish on them, but the other six were suffering from the disease. Mr. J. W. Embling gave his views on the diagnosis of small-pox, quoted Dr. Hadwen's opinion, and questioned Dr. Davison's competence, whereupon, after some further discussion, during which it was stated that Dr. Davison had been insulted in the street and threatened with personal violence, the Council unanimously passed a resolution tendering its warmest thanks to Dr. Davison for his valuable services, and, having the fullest confidence in his qualifications and administrative ability, urgently asked him to continue his services in Gloucester. After the meeting a deputation, which included the Mayor, the chairman of the Health Committee, and Mr. Embling, presented the resolution to Dr. Davison, who said that he could not disregard it and would continue to serve Gloucester for the period for which he had come. Dr. J. R. Bibby resigned, on June 30th, his position as medical officer of health for the city of Gloucester. It is understood that he intends to seek election, when opportunity occurs, to the Gloucester City Council, of which he was formerly a member. He was appointed medical officer of health for Gloucester in 1919.

A letter from Dr. Headlam, Bishop of Gloucester, was read in Gloucester Cathedral and in the churches throughout the city, on Sunday, July 1st.

So far, the Bishop wrote, the cases of small-pox had not been very serious, but in the great epidemic of twenty-seven years ago all the cases were at first mild, but later the deaths were appalling. He definitely declared the cause of the outbreak to be the neglect or refusal to be vaccinated. To refuse to be vaccinated was, he believed, wrong from a religious point of view. God had given them intellectual powers which enabled them to study the working of nature, and to learn the laws of nature. To refuse to obey His laws, to refuse to make use of the more certain results of medical science, and then to pray that they might have good health, was as wrong and foolish as it would be for a farmer to pray for good crops and refuse to cultivate the ground. Unless they could shake off the appeals to low motives, to party prejudice, to class prejudice, they could not hope to make the state of their city better.

During the week ending June 23rd, 1923, a total of 141 cases of small-pox were notified in England and Wales, according to the official *Weekly Return of Births, Deaths, etc.*, issued by the Registrar-General. The notifications were made up as follows:—Derbyshire—Alfreton, 1; Belper, 1; Heanor, 4; Long Eaton, 5; Clowne, 1. Durham: Stockton-on-Tees, 1. Gloucestershire: Gloucester (county borough), 79; Gloucester (rural district), 3; Cheltenham, 1; Stroud, 2; Westbury, 1; East Dean, 4. Hereford: Hereford (borough), 1. Notts: Kirkby-in-Ashfield, 6; Warsop, 15. Worcestershire: Martley, 1. Yorkshire: Middlesbrough, 1; Bentley, 2; Doncaster (rural district), 10. Monmouth: Risca, 1.

food. Absence of sunlight had also a great effect in the causation of rickets; experiments had shown that this effect was due to defective actinization of the air breathed by the animals leading to calcium phosphate retention in the tissues of the body.

#### THE SCOTTISH R.A.M.C. MEMORIAL.

The Scottish part of the war memorial to the 743<sup>rd</sup> officers and 6,130 other ranks of the Royal Army Medical Corps who lost their lives in the great war has just been carried to completion. The memorial in St. Giles's Cathedral, Edinburgh, was unveiled on June 30th by Lieut.-General Sir Walter Braithwaite, Commander-in-Chief, Scottish Command. It consists of a bronze tablet, with an angel of mercy at the top bending over a wounded soldier, and underneath, the crest of the R.A.M.C. The service of dedication was conducted by the Rev. Dr. Wallace Williamson. The memorial in Westminster Abbey was unveiled a year ago.

#### THE SCOTTISH BOARD OF HEALTH.

We referred briefly last week to the publication of the fourth annual report of the Scottish Board of Health, and indicated that the activities of the Board were to some extent limited during 1922 by the need of economy and by the prolonged trade depression. Employment showed scarcely any improvement as compared with 1921, and the Board found it necessary to extend for another year the operation of the Poor Law (Emergency Provisions) Act, 1921, which authorized parish councils to grant relief to destitute able-bodied unemployed and their families. This involved grants by ninety parishes in Scotland, amounting in all to £1,200,000 during the year.

The death rate for the year was 14.9 per 1,000 of population, which was 1.3 more than that of the previous year, but still 0.3 less than the mean of the rates for the previous ten years. There was a slight rise in the death rate from pulmonary tuberculosis (0.83 per 1,000, compared with 0.81 for 1921). The infant mortality rate was 101.4 per 1,000 births, which was 11.1 per 1,000 higher than in 1921, which, however, was the lowest rate recorded for Scotland. The estimated deaths per 1,000 children over one and under five years of age is 19.9, compared with 12.4 for 1921. The immediate causes of the increase were epidemics of measles, whooping-cough and "influenza" in the first half of the year. These figures bring out the deadly nature of the so-called "childish complaints," but the Board does not consider that it has sufficient data to determine the effect of unemployment upon this.

With regard to venereal diseases there seems to be a definite, if small, falling off in their incidence in Scotland. The infected persons who were treated in 1922 numbered 21,364, of whom 10,688 were still under treatment at the end of the year, and 4,759 were discharged cured. Just under one-half discontinued treatment without the sanction of the medical officer in charge. The treatment of venereal diseases involved an outlay of £65,782.

It is gratifying to note, especially in view of the prevalence of small-pox in some parts of England, that Scotland was practically free from the disease in 1922, only seven cases having been notified, all in the burgh of Kirkealdy. Small outbreaks of typhus fever occurred during the year in Glasgow, Saltcoats, and the islands of Raasay and Skye.

Regarding shortage of houses, the report states that if the estimates framed by the local authorities in 1919 are accurate, the housing problem in Scotland is still a long way from being solved. Indeed, the shortage is probably accumulating, for it is doubtful whether the number of houses being built each year is sufficient to provide for the natural increase of population and to replace houses that become unfit for occupation. Since there is no alternative accommodation for the occupants of these unfit houses, the local authorities are prevented from exercising their powers to close them. As a result, unfit houses remain occupied, to the detriment of the health and well-being of the occupants. The estimated number of houses

required in 1919 was 131,101, and by the end of 1922 only 14,777 had been completed, with a further 10,722 in course of erection. The Board believes that the present shortage in Scotland amounts to at least 100,000 houses. The Board notes an appreciable fall in building costs, so that the private builder has been enabled again to commence work.

#### EDINBURGH ASSOCIATION FOR SOCIAL STUDY.

The annual meeting of the Edinburgh Association for Social Study and Training was held in the Senate Hall of the University of Edinburgh on June 26th, Principal Sir Alfred Ewing in the chair. In the report for 1922, which was presented by the director, Miss Nora Milnes, special emphasis was laid upon the development of visitation in their homes of out-patients attending the Royal Infirmary. During the past three months 162 cases had been investigated and 280 visits paid. The report was cordially approved on the motion of Sir John Lorne Macleod, G.B.E. Thereafter an address was delivered by Miss Ida M. Cannon, director of Hospital Social Service, Massachusetts Hospital, Boston, United States of America. She said that in addition to the medical and research aspects of the hospital hitherto universally recognized, the hospital had a third and very important social function to discharge. She indicated the lines upon which this was being developed in the United States. Professor Sir Richard Lodge, one of the managers of the Royal Infirmary, in proposing a vote of thanks to Miss Cannon, said that in Edinburgh the social needs of in-patients had for long been well looked after by the Samaritan Society, and at the present time great efforts were being made to develop a social service on the lines indicated for the out-patients.

#### CENTRAL MIDWIVES BOARD FOR SCOTLAND.

At a meeting of the Central Midwives Board for Scotland for the hearing of penal cases, Dr. James Haig Ferguson in the chair, two nurses were found guilty of negligence and breaches of the rules. The Board instructed the instructing the removal of the name from the midwives' and issued an order that they be prohibited from attending women in childbirth in any other capacity. Another nurse appeared in answer to charges of failure to notify ophthalmia neonatorum in two cases, and other breaches of the rules. The Board found the charges to be proved, and expressed the opinion that the offences could not be adequately dealt with by censure or caution, but before instructing the removal of the name from the midwives' roll and the cancellation of her certificate, and in order to give an opportunity of proving amendment, it was decided to postpone a decision and to put the midwife on probation for report from the local supervising authority, and, in the event of an unfavourable report being received, instructions were given that the name would forthwith be removed from the roll and the certificate cancelled.

## Ireland.

The annual meeting of the Royal Medical Benevolent Fund Society of Ireland was held on June 20th, in the Royal College of Physicians, Dublin, when 76 cases were considered, and the sum of £1,462 was voted to 72 applicants.

#### IRISH COMMITTEE.

A meeting of the Irish Committee of the Association was held at the Irish Offices, 16, South Frederick Street, Dublin, on Wednesday, June 20th. Dr. Denis Walshe, chairman, presided and there were present: Dr. Joseph Power, Dr. J. Singleton Darling, Dr. H. T. Warnock, Dr. John Mills, Dr. T. B. Costello, Dr. R. C. Peacocke, and Dr. T. Hennessy, Irish Medical Secretary. Apologies for absence were received from Sir James Craig, M.D., T.D., Dr. H. Corby, Mr. R. J. Johnstone, F.R.C.S., and Dr. P. G. Lee. Dr. William Murphy, Dr. Joseph Power, and Dr. H. T. Warnock were co-opted members of the Committee. Dr. Denis Walshe was re-elected chairman, and Dr. John Mills

## PARLIER NOTIFICATION OF TUBERCULOSIS.

Sir,—At a recent conference between the members of the Public Health Council of the Council and representatives of the metropolitan borough councils, the question of the earlier notification of tuberculosis was considered. The conference passed a resolution as follows: That this conference is of opinion that the attention of the London Panel Committee and the British Medical Association should be called to the desirability of securing earlier notification of cases of tuberculosis, and that such information as is available should be forwarded to them.

Ministry of Health circular No. 194 (April 4th, 1921) suggested that, in order to secure prompt notification of cases under the Public Health (Tuberculosis) Regulations, 1912, metropolitan borough councils should once more direct the attention of the medical practitioners practising in their areas to the importance of strict compliance with their obligations under Article V of the regulations. Attention has more recently been drawn to the failure on the part of medical practitioners to notify cases of tuberculosis. Under the Public Health Act, 1866, penalties are recoverable for willful neglect or refusal to carry out the Tuberculosis Regulations; but after a long discussion of the matter at the conference, it was not considered that prosecution would be the most hopeful means for increasing the proportion of early notifications. The Council concurs in the resolution of the conference, and I am directed to communicate accordingly with the London Panel Committee and the British Medical Association, and to furnish to them the following summary of information obtained from the medical officers of health of the metropolitan boroughs:

No. dying from tuberculosis within one month of death.	No. dying from tuberculosis within three months of death.	No. dying from tuberculosis within six months of death.
During 1920: 5,086...	1,436 (29%)	239 (4%)
During 1921: 5,222...	1,637 (31%)	674 (12%)
During 1922: 5,222...	1,637 (31%)	674 (12%)
During 1923: 5,222...	1,637 (31%)	674 (12%)

In addition, I am to invite the London Panel Committee and the British Medical Association to direct the attention of their members to the fact that the services of the tuberculosis officers are available for consultation and for the examination of contacts, and that the Council has provided observation beds for the purpose of diagnosis. I am, etc.,

The County Hall, Westminster Bridge.

S.E.1, June 21st.

MOYSE H. COX,  
Deputy Clerk, L.C.C.

## OTHER VERSUS CHLOROFORM.

Sir,—It is a matter for congratulations that you have opened your columns to a discussion upon this subject, which, though treated in a somewhat academic fashion by some medical men, is of vital interest to the public. In the course of argument with my house-surgeons I have frequently been astounded by the remark, "Well, I have given some hundreds of anaesthetics, and I have only had one death from chloroform." One death! Only one family left without the breadwinner, only one woman deprived of her only child, only one husband left to mourn the loss of his wife! Oh, the tragedy of it! Year succeeds year and chloroform takes its toll of the population, and yet nothing is done to stop it.

My own experience of chloroform has convinced me that it is in any dilution a deadly drug, and that no previous examination, however stringent, can detect that unfortunate patient who has an idiosyncrasy regarding chloroform. My first introduction to its danger was when a student at St. Bartholomew's Hospital, a youngish man was given a chloroform by one of the staff anaesthetists to allow a catheter to be passed. The drug was administered drop by drop upon a nap of lint with ample air. Before a drachm There was nothing to be done; the heart had ceased to beat.

vice-chairman: Sir James Craig, Dr. J. S. Darling, Dr. W. Doolin, and Dr. R. C. Parvock were elected members of the Finance and Executive Subcommittee.

## Vote of Thanks to Sir James Craig, M.D.

Several members of the Committee and the Irish Medical Secretary referred to the great services rendered by Sir James Craig, M.D., to the furtherance of Irish public health and the interest of the profession generally since his election to the Dail as one of the members for Dublin University. The Irish Medical Secretary was directed to write to Sir James thanking him, on behalf of the Irish Committee, for his services in the Dail in connexion with medical questions.

## British Medical Association in Ireland.

The position of the Association in Ireland was considered in connexion with the different changes in the government of Ireland. The Committee was glad to notice that the change in Irish government seemed to make no difference in regard to the position of the British Medical Association in Ireland, and that the Association was functioning as heretofore throughout the country.

## Medico-Political.

The Committee considered the agenda of the Irish Medical Committee, and it was agreed to adopt and further the decisions of the Irish Medical Committee arrived at in accordance with the resolutions of the last meeting of delegates, representative of the entire Irish profession. The Committee also decided that the Irish Medical Secretary (Dr. J. Hennessey) should continue to act as honorary medical secretary of the Irish Medical Committee.

## Correspondence.

## "DIAPLYTE" VACCINES AND ANTIGENS.

Sir,—In my paper published in the last number of the *British Journal of Experimental Pathology* I gave an account of a method of preparing antigens from *B. tuberculosis* and some other Gram-positive bacteria, and I provisionally described the bacterial antigen so prepared as "defatted," a word that had been used conversationally in my laboratory. I pointed out at the same time that by the term "defatted" it was by no means intended to imply that all fatty or lipid substances present in the micro-organisms so treated had been removed. Only some of the lipid substances are taken away in this mode of preparation by washing with acetone after formalin treatment. It is plainly desirable, however, that the term "defatted" should not come into general use. It is as false, I am afraid, I propose to introduce a new word to describe the vaccines or antigens prepared by this or similar methods of extraction. The essential factors in the process are the fixation treatment by formalin and the successful acetone extraction which the bacteria so treated become, as I have described, non-acid-fast and Gram-negative, and are changed in appearance. They have been thoroughly washed out, and I propose to call them "diaplytes," from the Greek word *πλύνω*, washed, in its intensive form *διαπλύνω*, washed through and through. I propose to speak of "diaplytic vaccines" or "diaplytic antigens," and in the process of their preparation I should describe the acetone used as being the "diaplytic agent." I think there is justification for introducing a new word for the description of these vaccines, and it seems desirable to use one which has no previous connotations in pathology.—I am, etc.,

GEORGE DUNN.

Department of Pathology,  
University of Oxford, July 3rd.

'Some New Principles in Bacterial Immunity, their Experimental Foundations, and their Application to the Treatment of Infectious Diseases,' *Brit. Journ. Exper. Pathol.*, 1923, 4, 156.

Shortly afterwards two children died during induction with chloroform given for adenoid operations.

For the past sixteen years I have been on the staff of two general hospitals. In one chloroform is frequently used and there have been several deaths, mostly during induction. There was one death under ether, but this was a case of frontal sinus disease in an old decrepit man and a lot of blood was aspirated into his lungs. At the other general hospital ether is given. There has been one tragedy in ten years. A young, perfectly healthy girl was given chloroform to undergo a trivial operation. She died during induction. At the special hospital to which I am attached there has been one death in ten years, again chloroform. At the British Ophthalmic Hospital, Jerusalem, we used ether almost exclusively, given by an Arab boy educated in a mission school. We often performed twenty operations a day under ether, and I cannot remember a case that gave the slightest anxiety during the four years I worked there.

For the past sixteen years I have never employed chloroform, and I have extracted five cataracts under ether. I submit that if ether is suitable for cataract extraction, which demands absolute relaxation of the superior rectus, it will do for most operations. I absolutely forbid my house-surgeons to use chloroform in any dilution whatever without my permission—permission which I should never give unless the patient was one of those rare persons who cannot breathe ether. I tried the method advocated by Silk and McCardie: a mixture of one part of chloroform to sixteen of ether administered in a Clover apparatus. I very nearly had a fatality in the case of a young, perfectly healthy boy. We had to perform artificial respiration for twenty minutes.

The advantage of ether is that it is perfectly safe, I believe safer even than gas, and that it can be given by the semi-skilled. In Jerusalem we had an Arab boy, and he did all that was necessary. In America ether is given by a nurse. It can be administered without any apparatus, but I prefer to induce with a Clover, and to put 3 c.cm. of ethyl chloride into the bag. Unconsciousness supervenes in two or three minutes, and then we change to open ether. The alpha and omega of ether administration is to keep the jaw forward, and to give as little of the drug as possible.

My own experience is that ether is perfectly safe, and that chloroform is deadly. The constant records of deaths under chloroform confirm my view, and I think that the time has come when the Legislature should lay down stringent regulations regarding the administration of chloroform.—I am, etc.,

Leamington Spa, June 30th.

T. HARRISON BUTLER.

SIR,—There is no question that the periodical discussion on the respective merits or otherwise of chloroform and ether does help, by the pouring out for the anaesthetist's benefit the full vintage of the experience of many operators.

The advocates of each rather claim an anaesthetic Utopia for their favourite, and incidentally criticize the one they depreciate. Their praises of the merit of one is at the same time an indictment of the other. In spite of the lurid tones in which some depict chloroform, and though I also like ethanosal, I venture to support Dr. Samways in his appreciation of chloroform.

All surgeons, I believe, appreciate the quietness and relaxation that chloroform gives. Still, as Mr. Tilley remarks, the first and chief object is the safety of the patient. His experience seems to forge link to link to a chain in a way that rather prevents the remark that the chain has nothing to hold it. In fact, Mr. Tilley has conjured up the dread spectre of sudden death to scare the anaesthetist and drive him to ether.

I have heard that bronchitis and pulmonary sequelae do sometimes occur with ether; with chloroform such is not the case, I believe. Some patients, I am told, have died from post-ether pneumonia. These, of course, are not the subject of a coroner's investigation and so do not cast a slur on ether by being reported in the press. We may as well be candid and also, if possible, impartial.

Do I rub the sore when I should bring the plaster? I use and like both of these anaesthetics. Still, I would suggest that with a gradual induction, such as can be obtained with

a percentage inhaler, the dread spectre of sudden death can be exorcised.

For cerebellar operations, and all those in which the respiratory centre may be interfered with, and sepsis, where acidosis may be feared, chloroform is, I admit, not suitable. Still, there are shoals of other operations, and chloroform is a good net for many fish, and, with care, I venture to state none should escape without the requirements of the operator being fulfilled with absolute safety. Of course, the administrator must pay attention to his work and not monkey with the steering wheel over such a precipice as anaesthesia. If that is seen to I am sure the conclusion will be that chloroform cannot be slighted with impunity.—I am, etc.,

London, S.W., July 1st.

CHARLES T. W. HIRSCH.

SIR,—One afternoon, thirty and more years ago, I was sitting in the lowest tier of seats in the operating theatre of King's College Hospital watching the late Lord Lister tapping down the ends of the silver wire with which he was uniting the fragments of a fractured patella (then a new operation) rendered possible by his own faith in his new treatment of wounds.

His house-surgeon (*pro tem.*) was a recently qualified student who was giving chloroform. He had a white square of surgical lint, which he held pressed lightly over the patient's nostrils and opening of his mouth. Some remark caused Lister to look quickly at the patient, whose face had a waxy look, and who appeared to have stopped breathing. So quickly that we could hardly see what was happening, Lister had seized the astonished house-surgeon by the wrist, and the lint went flying away; at the same instant we saw the patient's lower jaw extended and his tongue hanging out over it with a pair of clipped forceps attached. Colour came slowly to the patient's face, and respiration could be seen. Lister gave a great sigh, and then, with that charming manner and sweet smile so characteristic of his fine face, he apologized to his house-surgeon for his apparent rudeness, saying, "The condition of the poor man demanded prompt action." Then he turned, and, facing a full theatre, said:

"Gentlemen, the method I consider to be the safest for administering chloroform is to pucker the pointed ends of a starched towel, or napkin, by passing a safety-pin through, and holding this well above the patient's nostrils and mouth in such a way that with each inhalation he obtains a free mixture of air during the whole time of administration. By observing this you will not require any form of apparatus, and the method is safe and simple."

I made a note of this at the time, and I now sometimes wonder, on so frequently reading of deaths under chloroform, whether the old teaching is still observed.—I am, etc.,

Birmingham, July 2nd.

J. B. MARTIN KENNEDY.

#### THE DIAGNOSIS OF SMALL-POX AND CHICKEN-POX.

SIR,—In the BRITISH MEDICAL JOURNAL of December 23rd, 1922 (page 1228), Dr. McConnell Wanklyn writes a very useful paper on the differential diagnosis between chicken-pox and small-pox. I presume he refers to modified small-pox—that is, occurring after vaccination—because it is usually in such cases the difficulty of diagnosis arises. Having suffered from small-pox personally, and after recovery seen a great number of cases in Dublin during my student days, I am able to confirm what Dr. Wanklyn says of the two eruptive diseases. There are two outstanding features which can be relied upon to assist in diagnosis. First, in variola the preliminary sickness is very marked and distressing, whilst in varicella it is not nearly so severe; and secondly, the path of invasion is generally quite evident and distinct. In small-pox the eruption is usually first observed on the extremities. The back of wrists and the forehead are two of the most favourite positions for the pimples or pustules to first appear, whilst in chicken-pox the chest, shoulders, and abdomen are the localities of selection for the eruption. In small-pox unmodified by previous vaccination there is

not suffering from any of these complaints, and to pronounce a verdict on them is very difficult. It is easy to say they should be enucleated, but to do so in every case must eventually bring discredit on the operation and the operator. I entirely agree with Mr. Tilley's statement that "it is impossible by mere inspection to say whether a tonsil is healthy or diseased." I hope the time will come when this assertion will be inaccurate. From certain passages in Dr. Poynton's lecture, I rather assumed that he considered it was possible, and it was more particularly to elicit this information that I raised the question.

The presence of enlarged lymphatic glands at the angle of the jaw is a very valuable sign, but there are many cases of obviously diseased tonsils where they are not palpable.

Dr. Cavenagh asks, "If 'pus' is not a sign of disease [in the tonsil] why should it be considered so in tooth sockets or accessory sinuses?" Surely there is no analogy. The more I study this subject, especially the transatlantic and Continental literature, the more convinced I become that the tonsils have a definite function to perform in resisting systemic invasion and in building up immunity. Professor Digby, whose researches, perhaps, are not so well known as they should be, describes in his letter in the *JOURNAL* of June 23rd (p. 1075) how he considers they do this. In his own words: "The lymphocytes in the tonsil are continually migrating through the epithelium, phagocytizing the bacteria in the crypts, and returning into the lymph nodules." In his book *Immunity in Health* he says: "Lymphocytes found astray in the lumen . . . are the few which have failed to wander back into the lymphoid tissue." We have therefore a fluid normally in the crypts which consists of micro-organisms, lymphocytes, shed epithelial cells, and mucus—clinically very like pus, but as it is formed by the tonsil in the exercise of its function, surely it is more physiological than pathological (a very different thing from pus in a tooth socket or accessory sinus, neither of which are lymphoid structures). The real practical difficulty is to distinguish between this physiological fluid (which has been mistaken for pus) and pus. If these findings are accepted the question of what is a diseased tonsil becomes very difficult to answer. In the present state of our knowledge, I think, only a physician can answer it if, after a thorough examination of all the systems of the patient, he finds evidence of systemic invasion, which is likely to have occurred through the tonsil.

The correspondence, to my mind, clearly shows that the problem has never been really tackled and that we have still much to learn.—I am, etc.,

Norwich, June 25th.

N. STUART CARRUTHERS.

#### THE EDUCATION OF MYOPES.

SIR.—The statement by Dr. Edridge-Green (June 30th, p. 1115) that "myopia is caused by distension of the eye due to back pressure through the veins, such as is caused by lifting a heavy weight," probably contains an element of truth, as my experience as oculist attached to medical boards during the war coincides with his in finding many cases of high myopia in farm servants, who are far from literary in their tastes.

That it does not state the whole truth is demonstrated by the case of a schoolgirl, aged 12, examined by me at Alford this year for the Aberdeenshire Education Authority. Under atropine her refraction was: Right eye -20 D.=6/18; left eye +1 D.=6/6. The fundus of the myopic eye was practically normal, with a very small crescent and no other lesion. Cases of anisometropia frequently repeat themselves in various members of a family; the same sort of astigmatism with the same axis may occasionally behave in a similar fashion. There is no doubt that heredity plays a very important part in the production of refractive errors. Nevertheless, careful correction and supervision of the education of a young myope is essential.—I am, etc.,

Aberdeen, June 30th.

A. RUDOLF GALLOWAY.

#### PROPOSED RONALD ROSS CLINIC.

SIR,—Your leading article and the recent letter in the *Times* concerning the proposal to establish in honour of Sir Ronald Ross a "Ronald Ross Clinic" leads me to write to you.

Sir Ronald Ross, whom I have had the great pleasure of knowing for many years, is deserving of the highest honour and recognition for the work so patiently pursued under difficulties, disappointments, and discouragements, to such a successful end. But may I venture to ask professional and informed opinion whether a clinic in a temperate climate is the proper place for research in tropical diseases, and whether the fund now proposed to be raised would not be much more advantageously expended in establishing one in a tropical country—India, for instance, where Sir Ronald Ross laid the foundations of his great work—or, perhaps, in endowing periodical expeditions to the tropics for the investigation on the spot of particular diseases or local forms of disease.

I make these suggestions with some hesitation, being only a layman who has been keenly interested for many years in the work of schools of tropical disease, and particularly in the establishment of the Sir Alfred Jones Laboratories at Sierra Leone.—I am, etc.,

Liverpool, June 29th.

J. PICKERING JONES.

#### FREEDOM OF NEGRO RACES FROM CANCER.

SIR,—Will you allow me to add the results of my own inquiries to Dr. F. P. Fouché's statement of the freedom of the South African native races from malignant disease (June 30th, p. 1116)?

Thirty years ago I was interested in the causation of cancer, when my friend, the late Sir Henry Morton Stanley, the African explorer, drew my attention to the fact he had observed, that the native races in the regions through which he had travelled were free from it. To make sure, he furnished me with a list of hospitals and got me to write to the physicians in charge of them. The replies I received confirmed his observation and revealed that only in coast towns, where natives mingled with Europeans, did cancer occur, and then only (at that time) one case in about ten or twelve years.

This information led me to further inquiries, and I ascertained that native races of other continents were similarly immune when not brought in contact with civilization. I also noted the belief of several of my correspondents that it was the vegetarian diet of the natives which accounted for the exemption.—I am, etc.,

London, W.1, June 29th.

BERNARD HOLLANDER.

#### HERPES ZOSTER WITH LOCALIZED MUSCULAR PARALYSIS.

SIR,—I am indebted to Dr. Parkes Weber (June 23rd, p. 1075), whose knowledge of the literature of the rarer manifestations of disease is unrivalled, for drawing attention to further references dealing with herpes zoster complicated by localized paralysis. In my paper, however, I commented upon the extreme rarity of cases of muscular paralysis in the affected zone accompanying or following herpes zoster of the trunk, and stated that I had found very few recorded cases.

By "herpes zoster of the trunk" I implied herpes due to involvement of any of the spinal ganglia between and including the second thoracic and twelfth thoracic segments, and used the term "trunk" as distinct from "limbs." I gave the few references to cases of paralysis of thoracic and abdominal muscles following herpes in the affected zone that I had been able to find, and also mentioned Ebstein's series of twenty cases of paralysis complicating herpes zoster, which included no case of paralysis of thoracic or abdominal muscles, merely to emphasize the rarity of the latter distribution. I made no attempt whatever to deal with the literature of paralysis of the limbs or shoulder-girdle muscles complicating herpes zoster, which I mentioned as being relatively more frequent owing to the closer association of the anterior and posterior spinal nerve roots in the lower cervical region than in the thoracic region.

## OBITUARY.

SIR JAMES REID, Bt., G.C.V.O., K.C.B., LL.D.,

F.R.C.P.,

Physician-in-Ordinary to the King.

We regret to record the death, on June 28th, at the age of 73, of Sir James Reid, Bt., G.C.V.O., K.C.B., Physician-in-Ordinary successively to Queen Victoria, King Edward VII, and King George.

James Reid, son of Dr. James Reid of Elton, Aberdeen-shire, was born in 1849, and was educated at the Grammar School of Aberdeen and then at the University of that city, where he graduated M.A. in 1869 with honours in natural science and a gold medal. He took the degrees of M.B. and D.C.M. three years later with highest honours, and the LL.D. in 1875. He practised in London for two years, and then returned home, he settled down in general practice as Elton, and in 1881 he was introduced into Court circles by Balmoral during the illness of Dr. William Marshall, who had been resident physician to Queen Victoria for several years. When it was seen that Dr. Marshall would be unable to take up his duties again, Dr. Reid was appointed in his stead and moved with the Court to London.

At first he acted under the supervision of Sir William Jenner, who for years paid a weekly visit to Queen Victoria except when the Court was in Scotland or abroad. Reid was undoubtedly an able and tactful man, and he soon gained the full confidence and respect of Sir William Jenner as well as of his patients. He proved very successful in what must have been a difficult position, and in 1867 was appointed Physician Extraordinary to the Queen. Sir William Jenner's health broke down about this time, and in 1869 Dr. Reid became in title, as well as in fact, Physician-in-Ordinary to Her Majesty. His duties at the Court occupied him fully, and as he was constantly in residence there he engaged in no other practice. The Queen thought very highly of Reid, and was accustomed to seek his advice in many matters not connected with medicine. She made him a C.B. in 1889, K.C.B. in 1895, and a baronet in 1897; in 1901 he was made G.C.V.O. A few years before her death the Queen bestowed on him a house within the precincts of Windsor Castle. After her death Reid continued as a Court physician, but the late Sir Francis Laking was rather the personal medical attendant of King Edward VII, and Reid attending often on Continental visits, and also taking part took a house in London. He relieved Laking at times, personal medical attendant of King Edward VII, and Reid resided always with the Court and was but little known to the medical profession, but after her death he lived in London and mixed more with his professional brethren, who were able to judge of his personal character and medical capacity, and formed high opinions of both. Reid became a Member of the Royal College of Physicians in 1887, and a Fellow in 1892. He was consulting physician to the King Edward VII Sanatorium, Midhurst. He received many decorations from the various Courts which he visited with Royal patients.

He married in 1899 the Hon. Susan Baring, daughter of Baron Revelstoke, one of the Aids of Honour to Queen Victoria, and leaves two sons and two daughters. His elder son and successor was a Page of Honour to King George, and distinguished himself at Cambridge, obtaining a first class in the classical tripos, Part II, last year.

A memorial service was held on July 2nd at the Chapel Royal, St. James's Palace, when the Archbishop of Canterbury officiated. A large congregation was present, including representatives of the King and Queen and other members of the Royal Family.

Sir, A recent decision in the King's Bench Division by Mr. Justice MacCardie on the need for house disinfection as an important factor in the control of tuberculosis raises issues regarding infectious disease and disinfection alike important to the practitioner of curative and of preventive medicine.

In their relation to disinfection, infectious diseases may be regarded as constituting three groups. The first group would include the majority of common infections—scarlet fever, measles, whooping cough, cerebro-spinal fever, and typhoid, from all of which infection is spread either from actual cases of the disease or from carriers, the infectivity of contacts being in all probability due to whether or not they happen to be carriers of the infection. The liability for fomites in this group to play the important part attributed to them in the past has less significance in the light of the current problem, and as a result the practice of house disinfection by chemical means after scarlet fever or diphtheria has now been largely given up as redundant or many medical officers of health. Chemical disinfection of an inhabited house fails therefore to control the spread of the above series of infections for two reasons: first, because no effect is produced upon carriers, who are mainly responsible for dissemination of the infection; and, secondly, because satisfactory disinfection of an inhabited house is in many cases wellnigh impossible without resorting to almost impracticable measures to ensure chemical cleanliness. Equal benefit has in these infections been found to result from disinfection of the fomites of the actual case, together with house cleansing, apart from any further attempts at disinfection by chemical means of the premises during occupancy.

In the next group the carrier is an invertebrate, actual cases of the disease apart from the carrier being non-infectious, as for example in typhus fever. Other examples of infections, though the common house, are due to infection spread both of which, like typhus, are due to infection spread through the common house. Disinfection and delousing are, therefore, of importance in controlling the dissemination of such diseases, destruction of the carrier being the most important part of the task of prevention.

A third group would be represented by tuberculosis dissemination in the pulmonary type, though infected sputum, whether recently exhaled or in dry dust months after its excretion. In the case of tuberculosis, with its absence of carrier, home disinfection can, with proper precautions, be carried out either after the removal of an infective case from his former surroundings, or, with greater satisfaction, should be enforced as a valuable public health measure, compulsorily, if necessary, when the premises are vacated. The ideal time to disinfect a house is on vacation, a fact that might well be considered by owners a matter of self-protection, before re-letting, in any case where a previous tenant is known to have had infectious disease in his household.

Apart from personal fomites care need only therefore be directed to the acquisition of ordinary domestic cleanliness and supervision of contacts in the first group, delousing whilst in the third domestic and chemical cleanliness should be carried out as effectively as possible, the absence of a carrier in tuberculosis being obviously an additional asset in the more effective control of this disease, by disinfection.—I am, etc.,

London, W., June 25th.

C. WORSSTER-DROUGHT.

K. SIMPSON, M.D., D.P.H.

Croydon, June 25th.

## THE RATIONALE OF PARATHYROID THERAPY.

BY

H. W. C. VINES, M.D.,

FELLOW OF CHRIST'S COLLEGE, CAMBRIDGE; FOULERTON  
RESEARCH STUDENT.

CHRONICITY of disease implies a stage in a pathological process at which neither the defence of the body nor the attack of the invading organism is making headway, but where the condition is that of an almost evenly balanced conflict. It is a balance between the effect of the parasite on the host and that of the host on the parasite, for in the first case the host has for some reason failed to respond sufficiently to the attack, and in the second the parasite is kept sufficiently in check to prevent an overwhelming onslaught. The main defence of the host lies in its cellular response, indicated by the mobilization of leucocytes and by the production of certain substances collectively called the antibodies. It is obvious that in chronic infections this response is insufficient to defeat the invading organism, and though it is easy to say that the resistance of the body has become weakened, such a statement explains nothing and affords no clue to the means of helping the body to victory.

It is impossible to assume that the reactions of the body to an infecting organism are limited merely to the mechanical mobilization of pre-existing cells and chemical substances. Both cells and antibodies are the end-products of other processes, for they must originate from some definite source, since neither is capable of reproduction in the blood stream. It is therefore behind these end-points of immune reaction that we must search for a clue to the failure of somatic response in chronic infections. Where the infection is of long standing, it is necessary materially to increase the rate of production of the leucocytes, and it cannot be assumed that the leucocyte-producing tissues alone of the body cells commence a proliferation due directly and entirely to the incidence of infection. Some means must therefore be found of stimulating certain tissue functions, and so the problem at once assumes a nutritional aspect. It may be recalled that the usual means of combating disease is by "keeping up the patient's strength"—that is to say, by decreasing tissue breakdown as far as possible by keeping the patient at rest, and by giving a nourishing diet; for many years therefore the basis of treatment of infections has been essentially the conservation of tissue energy.

## THE SYMPATHETIC RESPONSE TO DISEASE.

The non-volitional activities of the body—and among them immune reactions must be reckoned—are for the most part under the control of the autonomic system, and closely associated with the latter is the group of endocrine glands. Through the agency of this double system the metabolic tone of the body is kept at a standard level, which is recognized as the physiological normal, and since metabolism and resistance are so closely related it is not unreasonable to turn to this system in search of the cause of failure of the body to react to infective processes. The autonomic system and its associate glands are generally divided into two groups—the thoracico-lumbar or sympathetic system, with which are associated the thyroid, suprarenal, and pituitary glands; and the cranio-sacral or parasympathetic system, to which are conjoined the pancreas, the parathyroids, and perhaps the thymus. If now we consider the symptoms of an acute infection it is not difficult to see which of these two systems becomes first affected. Acute infection is accompanied by fever, tachycardia, shivering, sweating, increased metabolism, and hyperglycaemia; all these are signs of overaction of the sympathetic nervous system, and they may also be produced in some degree by overaction of the thyroid gland. If these symptoms are perpetuated the picture of a chronic wasting febrile disease is presented, and may be exemplified by the later stages of phthisis. The tendency of this syndrome is towards death, since the rate of katabolism is greater than that of anabolism, and therefore we find that the general

treatment of such conditions has been by rest and adequate nutrition, the indirect method of increasing resistance by limiting tissue breakdown.

There is another biochemical sign in acute infections which is of importance—it is the loss of calcium from the body; it has been recorded by a considerable number of observers and in a wide variety of diseases. There is evidence that this also is a sign of sympathetic overaction, for it may be produced by hyperthyroidism, while the parathyroid glands, which belong to the opposing system, are the regulators of calcium metabolism. I have observed disturbances of calcium metabolism in ulcerative conditions, and it has been shown that if the calcium deficiency which occurs is rectified by means of parathyroid administration the ulcer will also heal, the two processes running concurrently. Bruning and others consider that "trophic ulceration" is due to sympathetic overaction, and that while hypersympathicotonia leads to tissue degeneration and necrosis, vagotonia leads to tissue regeneration and repair. On these lines they treated a series of cases of varicose ulcer by periarterial sympathectomy and obtained satisfactory results. To sum up: the signs of sympathetic overaction include fever, tachycardia, sweating, hyperglycaemia, calcium loss, and a tendency to ulceration. All these are clinical signs of acute infection with the exception of the last, which, however, often appears in chronic infective states.

The acute infection has so far been considered, but it is easy to imagine a condition of less severity in which the symptoms are less marked and in which the infection is less acute. There may only be a low degree of fever, barely perceptible tachycardia, and yet the diagnosis of infection can often be proved bacteriologically. In such conditions some degree of hyperglycaemia and a decreased content of active calcium in the serum may be found, so that signs of sympathetic overaction are still present. We have now arrived at the picture of a chronic infection in which a low-grade sympathetic overaction is present, but yet in which the sympathetic function is greater than in the normal subject. For instance, in chronic nephritis there may be no clinical signs of sympathetic overaction, and yet calcium loss and hyperglycaemia have been frequently recorded.

Bacterial infection tends therefore to the disturbance of the balance between the sympathetic and the parasympathetic systems, the effect of the latter being outweighed by that of the former. If this be translated into terms of the endocrine glands, we may say that the thyroid overacts and submerges the action of the parathyroid glands. Examples of this antagonism are not uncommon, and it is frequently found that where a case is making progress on parathyroid therapy, the exhibition of thyroid substance will lead to retrogression.

## THYROID FUNCTION AND RESISTANCE.

It is quite clear that in infection the sympathetic system is first affected and that its main activity is an acceleration of metabolism together with increased efforts of elimination. This action cannot, however, be regarded as a purposive one, but it is more in the nature of an irritative effect by the bacterial toxins upon the sympathetic system. The question may even be raised whether the febrile response is of real assistance, and here the phenomena of immunizing animals may be of value. Sestini observed that the thyroid gland of guinea-pigs showed signs of hyperplasia and intense cellular activity against *B. typhosus*. Kepinow and .. . mented upon the tuberculin reaction in guinea-pigs and found that the febrile response was closely connected with the thyroid gland since thyroidectomy prevented its occurrence; removal of the thyroid did not, however, prevent the guinea-pigs from dying.

There is apparently no relation between the degree of febrile response which follows a vaccine injection and the degree of immunity thereby established, and it becomes questionable whether the febrile reaction is an advantage or the reverse. The results of the injection of a full dose of vaccine are parallel to a mild acute infection in regard to the clinical and biochemical signs, and in both instances

opposite type; a dose is given which stimulates the tissues weakened by tuberculous infection to increased vitality and enables the vitalized phagocytes to consume the tubercle bacilli, and, the active source of infection having been removed, to help absorption of the caseating material. It is unnecessary while a patient is having radium treatment to have the neck fixed so as to limit movement, or to make the patient in any way an invalid. Violent exercise only is prohibited, otherwise the patient is permitted to lead such a life as his general health will allow of, merely avoiding excessive strain and fatigue. The dose of radium employed appears to produce a general tonic effect on the system as well as a local effect on the glands; this I have gathered from the observations of several intelligent adults who have independently remarked on it, and have asked me whether the radium could have such an effect. Caution, diseased tonsils and adenoids, and any other obvious sources of primary infection, must be dealt with at the beginning of the treatment, as it would be folly to cure existing tuberculous glands and leave a future source of infection behind.

DISCUSSION.

The President said that many cures had been claimed which depended on mistaken diagnoses. It was difficult to realize that radium could cure tuberculous glands, but the fact that caseous glands had been present in many of Dr. Molyneux's cases was proof positive that they were tuberculous. He would like to ask how the cost of treatment compared with the cost of other methods such as operation. Would it be within the means of the ordinary individual?

Dr. NABARRO (London) called attention to the difficulty of distinguishing between tuberculous and syphilitic glands in children. A Wassermann test should be done in any doubtful case. Tuberculous glands were less common now than thirty years ago. He attributed this to the attention which was given to tonsils. Glands often subsided after their removal. The tonsil was a path of entry for the tubercle bacillus.

Dr. Molyneux, in reply, said that with regard to the cost he himself treated most cases free, but that it would certainly amount to less than the visit to the seaside, which was so often prescribed. He made certain of the diagnosis in doubtful cases by excising a gland and examining it microscopically; this had been done in a large proportion of his patients. A few had turned out to be Hodgkin's disease. These he refused to treat; it could do no good and might do harm. He had also had a number of cases of syphilis sent him. He always verified the diagnosis before attempting treatment. He agreed with Dr. Nabarro that removal of tonsils and adenoids often prevented the formation of tuberculous glands.

THE REACTION OF THE BLOOD IN CHILDREN.

BY  
RUTH CONWAY-FERNY, M.D., M.R.C.P.,  
Late Second Medical Registrar, Manchester Royal Infirmary.

In this communication, following the suggestion of A. V. Hill, the term  $\text{CH}$  will be used to represent the  $\text{H}$  ion concentration, thus omitting the use of logarithms. The  $\text{CH}$ , according to the Henderson-Hasselbalch equation, may be expressed as follows—

$$\text{CH} = \frac{[\text{HCO}_3]}{[\text{NaHCO}_3]} \times \frac{(\text{dissolved CO}_2 \text{ : to pr. CO}_2)}{(\text{combined CO}_2)}$$

By observing the  $\text{CH}$  in relation to the tension of  $\text{CO}_2$  and to the combined  $\text{CO}_2$ , we may have some idea of the factors controlling the acid-base balance. Among these factors the blood buffering power is of great importance. Dr. Cammidge has indicated the importance of the presence of buffer acids and buffer salts in the blood stream. I should like to emphasize the value of protein base salts found abundantly as base haemoglobinates in the blood; for example—

1.  $\text{NaHb} \rightleftharpoons \text{Na}^+ + \text{Hb}^-$   
2.  $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$   
3.  $\text{NaHCO}_3 \rightleftharpoons \text{Na}^+ + \text{HCO}_3^-$   
4.  $\text{H.Hb} \rightleftharpoons \text{H}^+ + \text{Hb}^-$

HUMAN BLOOD  
 $\text{CH} \times 10^{-7}$   
pathological acids present.

Fig. 1 shows the bloods of a number of normal individuals. Crosses indicate the arithmetical mean of readings of the  $\text{CH}$  at three mean observations of the  $\text{CO}_2$  content or combined  $\text{CO}_2$  value (alkali reserve). The two steeper curves are the  $\text{CH}-\text{v. CO}_2$  relation plotted in two cases of anaemia. Lack of haemoglobin allows the  $\text{CH}$  to increase more rapidly, or may be said to show failure of the  $\text{CO}_2$  content to rise as rapidly as in the normal. This shows the necessity of good buffering.

HUMAN BLOOD  
 $\text{CH} \times 10^{-7}$   
normal  
○ anaemic [normal and anaemic]  
\* average

If the  $\text{CO}_2$  tension be increased, then equation 2 will act from left to right, causing an increase in dissociated  $\text{H}$  ions,  $\text{H.Hb}$ , being weaker than  $\text{H}_2\text{CO}_3$ , tends to dissociate less, and equation 4 will take place from left to right, preventing increase of  $\text{H}$  ions. Reduction in  $\text{Hb}$  and  $\text{H}$  ions leaves equivalent amounts of  $\text{Na}$  ions and  $\text{HCO}_3$  ions—a neutral salt in solution. This will continue until the base available from  $\text{NaHb}$  is exhausted, and hence the importance of estimating the alkali available as base at more than one tension of  $\text{CO}_2$ . The power of a given blood to tolerate increases of  $\text{CO}_2$  tension and influx of carbonic acid can be observed by plotting the combined  $\text{CO}_2$  values at two different reactions. The latter are obtained by exposing a sample of blood to two widely differing  $\text{CO}_2$  tensions, and observing the  $\text{CH}$  and combined  $\text{CO}_2$  values at these tensions.

Fig. 2 shows the same relation in blood taken from children with post-anaesthetic ketonuria. It is presumed that a large part of the available alkali has been required to unite with acids produced by fatty fat and carbohydrate metabolism. Two cases treated with copious amounts of  $\text{NaHCO}_3$  solutions showed a lowered  $\text{CH}$  at any value of  $\text{v. CO}_2$ . In these cases lack of stimulus to the respiratory centre might cause oxygen lack, and would temporarily increase the alveolar  $\text{CO}_2$  provided no impairment of respiratory mechanism were present. It is hoped to define the normal limits of variation in these relations, and thus attempt to build up a method of prognosis concerning the blood of children about to be exposed to the risk of the presence of ketones and similar acids. I should like to express my thanks to Professor A. V. Hill, F.R.S., for his supervision and direction of this work, and I must also thank the committee of the Ashby Memorial Scholarship for permission to show cases investigated as work for this scholarship.

a negative phase of resistance is produced. The time of occurrence of the negative phase is coincident with that of the sympathetic response; in an acute infection vaccine therapy in the acute stage may have serious consequences, and an acute infection supervening in the negative phase after vaccine injection may be equally dangerous. There is no proof that thyroid overaction produces either maintained leucocytosis or favours the production of antibodies; such evidence as there is points to an opposite effect. It appears that the febrile response to infection has but little real value, except that it may aid in the elimination of a certain amount of toxic material by increasing the blood supply to the eliminative organs. It is also of interest to note that fever is usually regarded as a sign of danger and not of protection, that efforts are made to reduce it, and that the favourable course of disease is judged largely by the diminution of the intensity of the fever. Much has been written concerning the action of the thyroid as a "detoxicating organ," and though the statements are usually of a vague and indefinite character, there seems to be a gradually growing idea that the destruction of toxic substances occurs actually within the gland. No satisfactory proof of this theory has ever been forthcoming, and there is no evidence that thyroxin or thyroid gland can destroy toxic substances *in vitro*. The theory seems to be based largely on the hypertrophy of the thyroid in infections and in pregnancy, but the possibility does not seem to have been considered that such hypertrophy may be a reaction to chronic irritation, just as any other tissue may hypertrophy under similar conditions.

#### PARASYMPATHETIC FUNCTION.

Chronicity of infection may therefore be due in part to a continued overaction of the sympathetic system, and a simultaneous depression of parasympathetic activity which may be relative or absolute. It must also be remembered that the endocrine glands may suffer direct damage in disease and that their function may therefore be interfered with; in addition the function of the parasympathetic glands may be further affected by the thyroid hypersecretion. That such damage may be done to the parathyroid glands is shown by the not infrequent occurrence of tetany in acute and chronic toxic conditions. The function of the parasympathetic system is essentially towards the conservation of tissue energy, whereas that of the sympathetic is to accelerate metabolism even to the ultimate destruction of life. Normally these two systems are in equilibrium, and it seems reasonable to suppose that when this balance has been upset by infection one method of inducing adequate resistance to the disease will be to restore the endocrine balance to its normal state. It has already been pointed out that the sympathetic response to a vaccine injection does not produce a high degree of immunity, and that it is not until the sympathetic response is over that immunity becomes established. The injection of dead organisms limits the extent of the sympathetic response in point of time, but where an infection is present it is probable that the continuous irritation of the sympathetic system prevents, or at least delays, the re-establishment of the normal sympathetic-parasympathetic balance.

#### PARATHYROID FUNCTION AND RESISTANCE.

If this view of chronic infection is correct, the reasonable method of dealing with the condition is by increasing the parasympathetic function. If we regard the balance between the sympathetic and the parasympathetic as being represented by the balance between thyroid and parathyroid, then the means of counteracting thyroid overaction would be by parathyroid administration. The susceptibility of animals to infection after parathyroidectomy is well known; in common with other observers I have found that parathyroid therapy is of value in a wide variety of chronic infective states. In such different conditions as varicose ulcer, rheumatoid arthritis, and sprue, among others, it has been shown that an increase of the parasympathetic element by parathyroid therapy leads to a marked improvement. In such differing states there can be no question of any specific action of the preparation used upon the infecting organism, and it is evident that the phenomena of resistance to disease lie deeper than the leucocyte and the antibody. Moreover,

I have found that where a chronic infection is present and where the leucocyte count is low, the administration of parathyroid substance has led to a considerable increase in the leucocyte count, indicating an effect upon the leucocyte-producing tissues. Similar effects, but of a less decided character, may be obtained by the injection of soluble calcium salts, and this supports the statement that calcium loss is one of the signs of sympathetic overaction. It is of interest to note in this connexion the powerful action of ultra-violet light upon disorders of calcium metabolism such as rickets, and also the curative effect of sunlight on such chronic infective states as tuberculosis. One might conjecture that ultra-violet light has a depressant action upon the sympathetic system or that it stimulates the parasympathetic.

#### ENDOCRINE BALANCE.

It seems, therefore, that the problem of chronic infection resolves itself into the problem of equilibrium between the sympathetic and the parasympathetic systems, represented by the thyroid and the parathyroid glands respectively. It is not difficult on these lines to understand the incidence of chronic sequelae after acute infections, although the acute attack has apparently been overcome successfully and though the sequelae may be remote in point of time. The endocrine balance which was disturbed in the acute attack has never in reality returned to normal; a new equilibrium has been established on a different level which will still permit of an apparently normal existence. This new balance contains a sympathetic element greater than the normal, and signs of hyperthyroidism after severe illness are not uncommon. The patient is therefore left with a degree of parasympathetic deficiency and its accompanying susceptibility to infection. This is the condition which has been called "latent tetany," though a better term would be "chronic parathyroid insufficiency."

To recapitulate: the immediate response to infection, just as to physical attack, is an overaction of the sympathetic system. If the severity of the infection is of such a degree that it can be immediately overcome by the existing defences, there are no further ill results. If, however, the invading organism is not rapidly destroyed, the sympathetic irritation is continued and recovery does not take place or is long delayed; the condition becomes chronic, for under the existing condition of sympathetic overaction the resistant powers present at the onset of infection are not adequately reinforced. But if the activity of the parasympathetic can be stimulated, the re-establishment of the normal balance between the two systems permits recovery. As the body is kept in health by the normal balance between sympathetic and parasympathetic, so must this balance be re-established at the normal level for recovery to occur from an illness by which it has been disturbed.

Such a conclusion must lead to the consideration of all infective states on a similar basis, since the major phenomena of resistance to disease are not specific to the infecting organism in any sense of the word. The body reacts to all infections of equal severity in the same way—namely, by those phenomena which are collectively termed inflammation—and the only substances which are specific to the infecting organism are the antibodies. There is no evidence that these substances are produced to any great extent by the immediate sympathetic response, and experimental evidence suggests that thyroid activity does not facilitate their formation. They are a later development; in immunizing animals they appear after the negative phase at a time when the balance between sympathetic and parasympathetic is being restored. The leucocytes and the antibodies are not themselves necessarily affected by the disturbance of endocrine balance; the effect is upon the tissues as a whole, and therefore includes the sites of leucocyte production. In disease the body must be regarded as an organism with limited means of reaction, and it is those factors which control the physiologically normal state which will afford a clue to the control of abnormal or pathological conditions.

#### CONCLUSION.

The rationale of parathyroid therapy is therefore simple; it is a means of re-establishing the normal endocrine balance of the body, which infection has disturbed. Emphasis is

SECTION OF LARYNGOLOGY AND OTOTOLOGY.

DISCUSSION ON LABYRINTH DEAFNESS.

OPENING PAPER

DAN MCKENZIE, M.D., F.R.C.S.E.,

Surgeon, Central London and Ear Hospital; Otolaryngologist to the French Hospital, London.

There is probably no organ in the body the anatomy and physiology of which is so accurately, so intimately known to us as the labyrinth. But by an unparalleled concentration of circumstances there is no organ of the body of whose pathology, excluding suppurative, we know so little. The reasons for this regrettable state of matters, so strikingly at variance with modern medical progress, are simple. Opportunities for observing cases of deafness during their entire course from start to finish are rare. And still more rare are the opportunities of making a pathological examination of such cases at the different stages of their development, an examination which, we may add, demands from the investigator a quite unusual kind of skill, training, and experience. The time and the loved one seldom concur with the place when that place is the labyrinth.

We shall, of course, some day emerge from this darkness and myopic vision. But that day is not yet, and at the present moment, in a discussion which must necessarily range over the whole field of the non-suppurative diseases of the labyrinth, all we can do is to make the most of such pathological and clinical information as we possess. Unfortunately, whatever may be said of the scanty pathological data at our disposal, with regard to the clinical facts we have to confess that they are by no means always so clear and unequivocal as to render the conclusions we base upon them entirely trustworthy.

The first question we have to ask in a review which will be full of questions is: "What exactly do we mean by 'labyrinth deafness'?" If we were to address this question to a pathologist his reply would be simple and definitive, even although it might not carry the clinician very far in his search for enlightenment. "Labyrinth deafness," he would say, "is deafness caused by a disturbance in the labyrinth." But I am not speaking as a pathologist. I have no claim to do so. I speak as a clinician. I have no right to do so. I speak as an observer of clinical phenomena in general, and as such, looking back over a collection of many thousands of cases of deafness, I confess that I have often, very often, found it difficult and sometimes indeed impossible to tell, from the results of the hearing tests alone, whether the patient's deafness was due to a middle-ear lesion, to a labyrinthine lesion, or to both. And it is possible that most of my hearers and themselves in the same predicament as often as I do.

The textbooks of otology inform us, to be sure, and we who are teachers hand on the rule to our students, that there is a clean-cut distinction, traceable clinically by means of the hearing tests, between a defect in the conducting apparatus and a defect in the nerve organization of the ear. When, for example, in a deaf person, the hearing of tuning-fork sounds by bone conduction is increased, when deep musical tones cannot be heard, while the higher tones near Galton's whistle or the monochord are audible up to or beyond the physiological limit, then, we say, the deafness is "obstructive," and we are to infer that the impairment of function is due to a lesion situated somewhere in the conducting mechanism; whereas when the bone conduction is diminished, the deeper tones retained, and the higher tones lost, the deafness is "nerve," deafness, and it is to be attributed to a lesion in the nervous structures of the hearing organ.

Let, face to face with clinical fact, are we not compelled to admit that in nature this precise and comforting distinction does not always hold good? Nay, there are some who say to themselves that the distinction holds good but

very seldom, and that any inference based upon it as to the nature of the deafness is a mere guess.

In the first variety of deafness—the obstructive—when the phenomena I have mentioned are present, no one, so far as I know, has given any doubts upon the correctness of the inference. Obstructive deafness all acknowledged to be caused by a disturbance in the conducting mechanism of the ear. But this is by no means true of the second type, or "nerve" deafness. And there are undoubtedly grounds for a cautious, if not a sceptical, attitude here. To take only two instances out of many I have myself experienced, I have notes of a case before me as I write in which all the signs of nerve deafness were present, and of nerve deafness of a moderately severe grade. The patient happened to be a personal friend, and as was natural, I regarded the discovery, for I looked upon the impairment as serious. The external auditory meatus on both sides, it is true, was occluded by hard cerumen, but in view of my findings I was unable to promise myself or my patient much benefit from the removal of the mental obstruction. All the same the clearing of the meatuses was followed by the complete disappearance of every sign of even the slightest nerve or any other deafness. The second case I may mention was one of subacute Eustachian and middle-ear catarrh in which precisely the same happy ending was reached by the simple process of catheterizing the Eustachian tubes.

We are, therefore, compelled to admit that "nerve" deafness may be induced by a simple obstruction in the conducting apparatus. Or, to put the matter in another way, a lesion in the conducting apparatus does not inevitably produce the phenomena of "obstructive" deafness. Now I should like to ask you whether in your experience this disconcerting occurrence is a great rarity. We must pause here to note the fact that these criticisms are by no means novel. You will find them carefully and minutely dealt with in the literature of thirty years ago. And Lucæ it is who expressly cautions us not to rely upon the predominance of air conduction over bone conduction as indicative by itself of nerve deafness (that is, of a nerve disturbance) unless the hearing power is very much reduced. The whisper, he says, ought not to be audible at a distance of one metre. This, of course, is tantamount to saying that we are not in a position to diagnose from the tuning-fork test results any disease of the labyrinth, any case of nerve deafness, in its earlier stages. But this conclusion, though logical, need not dismay us. The deafness of nerve deafness, in its earlier stages, is of the classical "nerve" deafness variety. If, then, leaving ver-tigo out of account for the moment, the signs of "nerve" deafness are present, and if on a general survey of a case—the history, the subjective sensations, the objective appearances of the tympanic membrane, the nose, nasopharynx, and Eustachian orifices, and lastly the results of Eustachian manœuvres—we can find no sign of any middle-ear or mechanical disease, then surely we are entitled to say, in spite of its mildness, and maybe its brief duration, that the deafness is due to a disturbance in the nerve organization. Of course, this diagnosis can only be a probability. But the probability approaches more and more to a certainty as the point in the same direction. And of these findings one of the most important is the type of deafness present. This, then, is the proper use, and here is to be found the rationale, of the hearing tests. They form one of a large number of indications with their correlatives, otherwise they will, even in a non, mislead us.

I turn now to that very large group of cases in which the phenomena of nerve deafness as detailed above are present, but in which these phenomena are modified by associated obstructive deafness—what we call "mixed" deafness—where the bone conduction is diminished as compared with the physiological, but where a negative Rinne test shows the bone conduction as compensated with the patient's own aerial conduction to be increased. I think

laid on the point that the balance between sympathetic and parasympathetic must be brought back to normal level; adequate resistance to disease is not a function either of the sympathetic system or of the parasympathetic system, but of the equilibrium between them. Disease may occur equally when either system is overacting at the expense of the other, and it is probable that the great success of prophylactic vaccination as compared with the more meagre results of curative vaccination may depend on the fact that in the former case the subject is healthy and is in a state of endocrine equilibrium, whereas in the latter case other conditions prevail. Any tissue performs its functions best when under physiologically normal conditions, and it cannot be supposed that the tissues which are concerned in the mechanisms of defence are exceptions to this rule.

## EPIDEMIC HICCUP AND ENCEPHALITIS LETHARGICA.

REPORT OF A CASE OF EPIDEMIC ENCEPHALITIS SHOWING LETHARGY, CRANIAL NERVE PALSIES, MYOCLONUS, AND HICCUP,

BY

W. RUSSELL BRAIN, M.A., B.M., B.Ch. Oxon.,

HOUSE-PHYSICIAN TO THE MEDICAL UNIT, THE LONDON HOSPITAL.

THE purpose of this communication is to report a case of epidemic encephalitis exhibiting in one individual many of the varied manifestations of this protean disease.

M. M., aged 16, a healthy-looking well developed girl, was admitted to the London Hospital on July 18th, 1923. The mother says she had St. Vitus's dance as a child. In November, 1918, she had an acute illness. She was in bed a week with severe headache, sleepy all day but restless at night, and delirious for a day or two. She did not complain of visual impairment or diplopia at that time. Drooping of the right eyelid was noted by the doctor who attended her, but the mother said it has been present since infancy, and this is corroborated by photographs. She made a good recovery. This was possibly a previous attack of encephalitis.

Three months before admission she began to have attacks of hiccup two or three times a week; the attack would last a few minutes and then stop spontaneously.

Two months before admission she became acutely ill with severe headache. She slept all day, was hard to rouse, and became "a little light-headed at night." She vomited several times and the temperature is said to have been 104° F. She was in bed two days, and on getting up found that objects looked blurred, and she saw double, and has done so ever since—has felt languid and has had occasional attacks of hiccup as before.

Eight days before admission an attack of hiccup began which continued until admission; and she did not sleep at all on the previous night. The mother states that the patient has been always rather excitable, but more so since her illness two months ago.

### Condition on Admission.

**Mental State.**—On admission she was restless, excitable, and talkative; smiling and laughing during examination. In spite of having hiccupped persistently for eight days she was apparently in no way depressed or fatigued by her condition, but, on the other hand, was rather amused at it; she was able to give an intelligent account of her illness; and her memory was unimpaired. Her mental state was thus similar to that of the myoclonic cases described by Ellis, though the excitement was less extreme and there was no delirium.

**Hiccup.**—When admitted she was hiccupping about 120 times a minute. Synchronous with each contraction of the diaphragm was a relaxation of the musculature of the abdominal wall and a sharp dilatation of the alae nasi. The frequency of the hiccup was diminished during speech, but it was not completely inhibited and often cut short a word; laughter caused a similar partial inhibition. She complained of a sensation of stiffness around the lower ribs. The hiccup ceased as soon as she was given a hot bath, within two hours of admission, and before she had had any sedative drug.

**Myoclonic movements** occurred in the upper limbs and the abdominal walls, but have never been very marked. In the upper limbs there were slight jerking movements of flexion of the elbow, wrist, and fingers, and pronation of the forearm occurring every few seconds. In the abdomen even before the hiccup ceased slight twitches of the abdominal muscles were seen, which did not occur so frequently and did not synchronize with it. When the hiccup ceased it was possible to examine these movements alone. They occurred seven or eight times a minute almost entirely in the upper abdomen and chiefly in the upper right quadrant, the umbilicus being drawn sometimes straight upwards, but usually obliquely upwards and to the right. The movements were associated with a weakness of the upper abdominal wall for voluntary movement, the umbilicus moving downwards when the head was

raised from the pillow against resistance. The abdominal reflexes are of interest; the response in the right upper segment was very brisk as compared with the reactions in the other segments, and consisted of a sharp primary twitch, followed by a series of smaller twitches occurring at irregular intervals for several seconds. The reflexes on the left side and in the lower segments on the right side were normal. The myoclonic movements were thus associated with an increased reflex excitability of the same segment of the abdominal wall.

**Cranial Nerves.**—The fundi were normal, vision was unimpaired, and the visual fields normal.

There was an extremely sluggish and unsustained reaction to light and on accommodation, but a slightly brisker response on convergence, which was poorly carried out. There was a slight weakness of the external rectus on each side with a corresponding convergent strabismus and diplopia on extreme lateral fixation to either side. Slight ptosis of right eyelid. No nystagmus. The uvula was drawn to the right on phonation. The other cranial nerves and the remainder of the nervous system showed no abnormality.

### Condition One Month after Admission.

She had had no recurrence of the hiccup (August 15th), but was still abnormally sleepy at times, and occasionally complained of pain behind the eyes. The mental excitability was less pronounced, but the myoclonic movements were slightly more marked. Involuntary elevation of the eyebrows and blinking of the eyes were noted, while, in addition to the movements described before, occasional contractions were observed in the sternomastoids, the pectorales, the small muscles of the hands, and both quadriceps extensors; flexion and extension of the toes also occurred. The abdominal movements were unchanged; there was some flattening of the right upper segment on raising the head against resistance; the abdominal reflexes were brisker on the right than on the left, especially in the right upper segment, where the response still consisted of a series of three or four successive twitches. The cranial nerve palsies were less marked. The response of the pupils to light was brisker, as was also the reaction on convergence. The reaction on accommodation was still sluggish and ill sustained. Photophobia was still present. The weakness of the external recti was extremely slight, there being now no obvious strabismus, and only slight blurring of the image on extreme lateral fixation to either side. The slight ptosis of the right eyelid was unchanged.

When in 1917 von Economo first described the condition the well known lethargic type of the disease, with somnolence, lethargy, and ocular palsies leading to ptosis, strabismus, and pupillary disturbances, greatly predominated. Later it began to be realized that the manifestations were much more varied and widespread. The occurrence of cases closely resembling paralysis agitans began to attract attention, and still later the excited and myoclonic and choreiform types of the disease and the occurrence of epidemic hiccup became recognized.

In the excited and myoclonic patients and in epidemic hiccup the lethargy so typical of the more ordinary forms of the disease is replaced by mental excitement, delirium, and insomnia. Cases in which myoclonic movements were present occurred sporadically in 1918, but it was not until the end of 1919 that they became prevalent. They were described as a form of acute epidemic encephalitis in January, 1920, by Sicard and Kudelski, and Ellis<sup>1</sup> reported three cases in this country in that year. The characteristic of this variety is the occurrence of twitching of the muscles of the limbs, and rhythmic shock-like movements of the abdominal muscles, which may be so severe as to shake the bed with each contraction. Cranial nerve palsies may or may not occur.

Although cases of hiccup were noted by von Economo in 1917, hiccup did not occur in epidemic form until the end of 1919, when an outbreak coincided with the epidemic of the myoclonic form. Hall<sup>2</sup> quotes Boyd as describing an outbreak of epidemic hiccup which occurred in Winnipeg in the autumn of 1919, and preceded an outbreak of the lethargic form of the disease. The same authority quotes Dargein and Plazy, who describe a case in which lethargy and ocular palsies developed a fortnight after recovery from an attack of epidemic hiccup. But Hall concludes that "at the present time no dogmatic statement of the relationship of the two conditions seems warranted."

### CONCLUSION.

The above case, therefore, is of interest. The patient after suffering for a month from intermittent brief attacks of hiccup, developed a typical though mild attack of the lethargic form of encephalitis with ocular

all will assent to the statement that this is the commonest type of deafness we encounter. Dundas-Grant, by the way, pointed out many years ago that there is a preponderance of bone conduction over air conduction not only when the Rinne test is negative, but also when it is zero. He goes so far as to make the same decision when the Rinne test, though positive, is less than the normal length for any particular fork.

Fortunately, as we have already said, in making our diagnosis in any case of deafness we are not limited in our examination of the patient to the hearing tests alone. The history of the case tells, perhaps, of attacks, it may be many years before, of nasal or nasopharyngeal disease; we learn, maybe, that the deafness varies with the weather, that our objective examination may reveal changes in the Eustachian tube or tympanic cavity. The upshot is that we are able to say confidently, in most cases of mixed deafness, that whether there is or there is not a lesion or a defect in the labyrinth, there are certainly changes in the conducting apparatus sufficiently great to cause considerable deafness.

But how are we to account for the presence of the signs of nerve deafness? Now we know as certainly as we can know anything that a lesion limited to the labyrinth does induce the phenomena we call pure nerve deafness. We are, therefore, entitled to suppose—though to be sure it is only a supposition—that when nerve deafness is present in a case of mental obstruction or middle-ear disease, whether that nerve deafness is pure or mixed, so long as the general deafness is pronounced, we are entitled to suppose, I say, that these obstructing lesions in some way lead to a disturbance in the cochlea. How do they do so, and what is the disturbance they cause?

In many cases, no doubt, cases (say) of serious and it may be long-continued disease in the middle ear, the pathological process extends to and implicates the labyrinth. Microscopic examination has frequently disclosed in such cases as these degenerative processes in the cochlear structures. But it is necessary to recall to your memory that, according to Politzer, the labyrinth is not affected save in the "chronic adhesive processes" of the middle ear, and in otosclerosis, and in syphilis. In chronic non-purulent middle-ear catarrh the labyrinth, "except in rare cases," is, we are told, undamaged. There is, however, a great deal to be said for the active participation of the labyrinth in middle-ear disease. The frequent occurrence of spontaneous nystagmus in acute suppurative of the middle ear proves the readiness with which lesions in the one will influence the functions of the other.

As to the manner in which simple lesions of the conducting apparatus unaccompanied by cochlear changes may induce the phenomena we usually associate, and with reason, with cochlear and other diseases I am ignorant. Here we come upon one of the gaps in our knowledge. Perhaps the defect in the cochlea, seeing that the phenomena disappear with the obstruction, is only functional. On the other hand, there may be some varieties of obstruction which, without affecting the cochlea at all, induce of themselves what we call nerve deafness. As things are at present this may seem to be a large assumption to make; nevertheless there are many authorities who subscribe to this opinion.

Leaving all such theoretical considerations on one side and turning to clinical facts, there is, as my figures show, one generalization formed from these facts which we may safely venture upon, and that is that the most common cause of nerve deafness known to us, whether that nerve deafness be due to an organic or to a functional cochlear change—the commonest individual cause of nerve deafness—is middle-ear disease.

Let us now inquire whether the foregoing critical considerations have any practical meaning for us. It has often been said—it is to any almost an otological truism—that when objective middle-ear disease are present, and when the typical obstructive deafness of such a case is modified by the presence of the phenomena of nerve deafness, then the prognosis is unfavorable. In so far as this applies to the cure of severe deafness in chronic cases I agree. But to say that such findings invariably fore-

shadow a progressive deterioration of hearing would, in my opinion, be going too far—save, perhaps, in otosclerosis. Doubtless in many cases progress downward does continue. On the other hand, I am inclined to say that if the disease process in the middle ear can be arrested then the deafness, even when it manifests some of the signs of nerve deafness, may become stationary, at all events until the patient reaches old age. In support of this statement I can cite instances from my own practice; I know patients whose deafness has remained thus stationary for the last fifteen years. We should, therefore, avoid taking too gloomy a view of nerve deafness when middle-ear disease is present if—and the proviso is important—if the middle-ear disease is of a kind likely to be brought to a period by treatment. Before we leave the subject of mixed obstructive and nerve deafness it is necessary to consider one variety of this class which is continually amenable to treatment. I allude to myxoedematous deafness. There are some otologists who, they tell me, make a practice of substituting all cases of mixed deafness to a course of thyroid medication, and this practice has much to commend it. For deafness seems to be often quite an early phenomenon in myxoedema, and the response to thyroid treatment may give us a pleasant surprise. Altyxoedematous deafness has another lesson for us: it shows that middle-ear and labyrinth deafness may coexist—not because one is induced by the other, but because both are due to a common cause. The same lesson, by the way, may be learned from otosclerosis. I suppose you will agree that, speaking generally, all high grades of deafness show signs of involvement of the labyrinth. At all events, the upper tone limit is lowered and bone conduction shortened. And, *a fortiori*, when a patient is deaf to all sound by air we expect to find those signs of nerve deafness very pronounced. Nevertheless, I once had an opportunity of examining a lady, who had been deaf for forty years to all sound but whom, in whom the bone conduction was actually increased. In view of the fact that condition was as the perceptive mechanism remains intact some amount of hearing must persist, this case is hard to explain except on the assumption of a functional defect either in the end-organ or in the cerebral hearing centre. It is a curious circumstance, by the way, that labyrinth disease in adult life but seldom leads to complete abolition of function. Some amount of hearing even in the worst cases is left, although it may be but a trifling amount and of no practical value to the sufferer. Of non-purulent deafness affecting both ears progressive nerve deafness, syphilis, and epidemic meningitis alone are liable to end in absolute deafness; while, though herpes often and mumps lead to complete deafness, it is less crippling in that it is only unilateral. The condition of the vestibular reactions in suspected labyrinth deafness, it is less crippling in that it is only unilateral. I have paid some little attention, broadly speaking, to nerve deafness, as evidenced in the phenomena of nerve deafness, is associated with impairment or complete abolition of the vestibular reflexes. And when this is the case we may look upon it as suggestive at least of some organic disease of the vestibular apparatus. Because clinical experience has shown us that the canalicular section of the labyrinth is very frequently indeed affected, in some way not yet understood, by serious cochlear trouble. It is necessary, however, to add the caution that, as with the hearing tests, so with these reactions, considerable variety is encountered in practice. Everyone has noticed, of course, how acute disease of the labyrinth is accompanied by attacks of severe and it may be prolonged vertigo, whereas, on the other hand, in chronic labyrinthitis is accompanied by attacks of severe and it may be prolonged vertigo, while, as I have just said, the vestibular reactions are often impaired, vertigo—at all events severe reactions—may be entirely absent. According to my figures vertigo of the "storm" type was present only in about 11 per cent. of the cases of pure nerve deafness. Now it is remarkable that in mumps deafness, the attack, albeit often dramatically sudden and complete, is not accompanied with vertigo nor with impairment of the vestibular reactions. Here we come upon another of those gaps in our pathology. The lesion that causes mumps deafness is unknown. But our clinical experience permits us to surmise that the lesion is either not situated in the labyrinth, or, if it is, then the progress is unfavorable. In so far as this applies to the cure of severe deafness in chronic cases I agree. But to say that such findings invariably fore-

palsies. Two months later, after further brief attacks of hiccup, an attack of hiccup developed which lasted eight days, and for which she was admitted to the London Hospital. On admission she exhibited cranial nerve palsies, hiccup, and also myoclonic movements of the arms and abdominal wall. This would seem to establish finally the relationship between epidemic hiccup and epidemic encephalitis.

It is therefore not surprising that the epidemics of hiccup and myoclonic encephalitis should have coincided in 1919, since hiccup is probably a myoclonus of the diaphragm. In this patient as in the case recorded by Dargein and Plazy the hiccup preceded the development of the lethargic symptoms.

A further point of interest is the occurrence in this patient of an acute illness with lethargy and delirium in November, 1918. If, on the rather scanty evidence obtainable, this be accepted as a previous attack of epidemic encephalitis, the present illness must be regarded as a recurrence of the disease after the long interval of four years and six months.

It will be seen that in this one patient the majority of the varying types of this interesting disease are apparent and that the history of the individual reproduces more or less accurately the history of the development of our knowledge of epidemic encephalitis.

## DISCUSSION ON SUMMER DIARRHOEA.

## OPENING PAPER

BY

DAVID NABARRO, M.D., F.R.C.P. LOND.,

Director of Pathological Department and Bacteriologist, Hospital for Sick Children, Great Ormond Street, W.C.

SINCE the early days of scientific bacteriology many investigators have paid attention to the micro-organisms present in cases of summer diarrhoea with the view of isolating the causal agent. Some of the earliest investigations are of little more than historical interest, inasmuch as the differentiation of allied forms as we now know them was in its infancy. I have not the time or space at my disposal to give you a detailed account of all the investigations which have been carried out upon this subject, so shall content myself by giving a summary of the findings of previous investigators.

Booker and Escherich were among the first to study the flora in intestinal disease, but they did not find a specific organism for diarrhoea. Amongst the organisms isolated by Booker were *B. coli communis*, *B. lactis aerogenes*, *B. proteus vulgaris*, and streptococci, any one of which Booker thought might play a part in the different types of the disease studied by him.

Klein in 1897 and 1898 isolated the *B. enteritidis sporogenes* from a small number of cases and regarded it as the causal organism of summer diarrhoea.

It was about this time (1898-1900) that Shiga, Kruse, and Flexner discovered the bacillus of dysentery, and in 1902 Duval and Bassett isolated dysentery bacilli from 42 out of 53 cases of infantile diarrhoea. These authors come to the conclusion that the dysentery bacillus "is an important, if not the most important, cause of summer diarrhoea in children." In 1903 the Rockefeller Institute undertook, under Dr. Flexner's direction, a comprehensive investigation in several large American cities on the occurrence of the dysentery bacillus in the summer diarrhoea and other

diarrhoeal diseases of children. Dysentery bacilli were isolated in 63.2 per cent. of the 412 cases investigated. They were mainly of the Flexner-Harris type, but the Shiga type was also met with, and occasionally the two types were associated. Other atypical forms were also isolated. Flexner, in his conclusions, stated that it is probable, though not proven, that *B. dysenteriae* appears at times among the saprophytic bacteria of the intestinal contents. He states also that streptococci in large numbers were frequently grown together with the dysentery bacilli, but that the relative parts played by each in the production of the intestinal lesions and the symptoms of the disease is not established by the investigation. Nor is the possible action of any other of the many bacteria of the discharges excluded by the special findings of this investigation. Other American observers, among them Wollstein, Park Collins and Goodwin, Duval and Schorer, Cordes, Weaver and Tunnicliffe, and Graham of Toronto, have reported epidemics associated with the dysentery bacillus.

In connexion with the frequent isolation of the dysentery bacillus by many American observers and its rarity in our English cases of the disease, attention must be drawn to the fact that the clinical types of summer diarrhoea as studied in the two countries appear to differ. In the American type of case the stools very frequently contained blood and mucus, and hence were more like the stools passed in true epidemic or asylum dysentery. In cases seen in this country the stools are variously described as green, slimy, watery or curdy, and offensive; blood is only occasionally present and mucus perhaps more frequently.

On the other hand, we find that Park Collins and Goodwin, and Schwarz in America, and Jehle and Charleton in Vienna, never isolated dysentery bacilli from cases of acute gastro-enteritis with the characteristic stools we are familiar with in this country. The last named observers considered that summer diarrhoea might be caused by various forms of micro-organisms of a non-dysenteric type, more particularly by *B. coli communis*.

In 1905 and 1906 Morgan studied the bacteriology of the disease in London children and isolated a considerable number of bacilli of the non-lactose fermenting type. These investigations were continued by Morgan and Ledingham in 1907 and 1908, and their presentation of the results obtained and the conclusions they drew from them to the Epidemiological Section of the Royal Society of Medicine in February, 1909, evoked an interesting discussion from epidemiologists and bacteriologists.

The outcome of the prolonged investigation was that a certain organism—Morgan's No. 1 bacillus—was proved to occupy a predominant position among the non-lactose fermenters in the excreta of summer diarrhoea patients. "In selected cases of the disease" it was isolated from 63 per cent. The strains isolated in 1905 and 1906 were pathogenic to young rats, rabbits, and monkeys by feeding; diarrhoea was produced, followed by death. The 1907 and 1908 strains were found to be much less pathogenic to animals by feeding.

Agglutination reactions with the serums of patients yielded far less satisfactory results than had been obtained by the American investigators. In 1905 Morgan found only one of the 44 serums tested agglutinating its own bacillus. In 1908 positive results were obtained in a larger proportion of the cases, 50 out of 65 cases tested giving a positive reaction with Morgan's bacillus, but the dilution in which the reaction was obtained never exceeded 1 in 40. The best results were obtained at or near convalescence.

Morgan's bacillus is a motile, small, Gram-negative organism which grows well on ordinary media, produces acid and a little gas in glucose and no change in lactose, dextrose, saccharose, or mannite. Litmus milk is unchanged in one and three days, but slightly alkaline on the fifteenth day. Indole is produced and gelatin is not liquefied. Morgan and Ledingham came across two variants of this type, both of which were non-motile and one of them not producing indole. It will be noted that the variant which was non-motile and indole-negative differs from Shiga's dysentery bacillus only by the production of a little gas in glucose media. Morgan himself, in his 1907 paper, draws attention to the fact that some of the properties of his No. 1 bacillus may vary—particularly the amount of gas produced from glucose. This, he says, may be so slight that

none shows in an ordinary Durham's tube. He notes, too, that the gas-producing power varies with age; after eighteen months' subculturing there may be no gas produced.

Another point from Morgan's and Ledingham's researches deserves attention. In addition to Morgan's bacillus and its two variants just referred to, no less than thirty-one other strains of non-lactose fermenters were encountered. These are grouped by the authors into seven types, which include a Flexner and a Gaertner type, each of which contains several strains and varieties.

The question of a filter-passing virus as the infecting agent was also considered in 1908. The blood and organs from three fatal cases of typical summer diarrhoea were extracted with salt solution and passed through a Berkefeld filter. Young cats were fed and rats inoculated with the filtrate, but with entirely negative results.

In 1907 Orr and his collaborators isolated from the heart blood, taken immediately after death from a fatal case of summer diarrhoea, an organism of the *Salmonella* type. It produced no change in litmus milk and no indole. It was pathogenic to the ordinary laboratory animals on injection and to puppies by feeding. In a later paper (1910) these investigators report that in course of time they found a gradually developing alkalinity in milk cultures and also that the bacillus formed gas from galactose, whereas on isolation it had formed acid alone. From 40 cases of summer diarrhoea they isolated this bacillus seventeen times, and they state that it was not once isolated from 100 healthy infants and children. They call it *Bacillus "F,"* and consider that agglutinogenically it is related to *B. paratyphosus B* and *B. suispestifer*.

Next in point of time (1910-12) came the investigations of Lewis, Alexander, Ross, O'Brien, and Orr, under the auspices of the Local Government Board, to examine, amongst other points, the incidence of Morgan's No. 1 bacillus in healthy infants and children and in those suffering from diarrhoea; 919 normal children were examined in London, Birmingham, Liverpool, Manchester, and Shrewsbury, with the result that non-lactose fermenters were isolated from the faeces of 212 (23 per cent.). These organisms were of many different groups and varieties, the commonest being Morgan's No. 1 bacillus, which was isolated from 44 cases—about 4.8 per cent. Other non-lactose fermenters isolated from these normal cases were Gaertner's bacillus (Ross), Shiga's bacillus (Orr), and "dysentery-like" bacilli (Alexander). An interesting observation of these investigators, emphasized by Lewis, was that non-lactose fermenters were most often found in cases where cow's milk was an important item in the dietary, and when cow's milk was the sole diet such bacilli were rarely absent.

During these investigations (1910-12) 659 cases of summer diarrhoea were examined and non-lactose fermenters were obtained from 405—giving a percentage of 61.4. By far the commonest non-lactose fermenter encountered was Morgan's No. 1 bacillus (182 times); next comes Lewis's Group H (36 strains), then *B. paratyphosus B* and Gaertner (10), and *B. dysenteriae* (8). The remaining 169 non-lactose fermenters are distributed in various groups, subgroups, and varieties. Similar organisms were also isolated from milk, mice, and flies, so that it was concluded (1) that there are habitats for these organisms outside the human body, (2) that milk may serve as a vehicle, and (3) that other avenues may exist by which these organisms may gain access to the alimentary canal of children. Lewis (1914) after investigating the agglutination reactions of 242 strains of Morgan's bacillus, came to the conclusion that there are at least three main groups which can be thus differentiated, and that the strains isolated from normal children, from milk, and from mice may exhibit agglutination reactions identical with those of Morgan No. 1 isolated from diarrhoea cases. Logan in Edinburgh (1912) isolated non-lactose fermenters from 6 out of 21 normal children who were artificially fed. He did not find them in breast-fed infants. Morgan's bacillus was isolated twice; the others belonged to Lewis's groups H and J. In 14 cases of summer diarrhoea he met with Morgan's No. 1 bacillus 5 times, and from 3 others he isolated non-agglutinable dysentery bacilli. In one case numerous *B. proteus* were found. He records an interesting observation of "four cases all in the ward at the same time and three of them starting acute diarrhoea

within a period of three days, in which the non-lactose fermenters isolated were different in each case."

We come next to the claims of *B. proteus vulgaris* as a cause of summer diarrhoea. It has already been mentioned that Booker assigned an important rôle to this organism in some of his cases. Jeffries and Baginsky also concluded that it played a part, but they do not suggest it as the sole cause. Most subsequent observers, too, have come across *B. proteus* in a certain small proportion of their cases. Metchnikoff and his school revived the suggestion of the causal relationship of *B. proteus* to summer diarrhoea. In 1914 he wrote thus: "*B. proteus* is the chief microbe in the diarrhoea of infants. We have found it in nearly every case of the disease we examined. Its pathogenicity when given by the mouth, either alone or in association with other microbes, demonstrates its preponderating importance." Several investigators, such as Levy and Thomas (1895), Vincent (1909), and Metchnikoff and Berthelot (1914), have shown that *B. proteus* seems to possess the power of increasing the pathogenicity of other organisms. Apparently in certain French epidemics of this disease *B. proteus* has been much more frequently found than in the cases studied in other countries.

Bloch (1911-18) reports the isolation of *B. proteus* in 52 out of 128 cases of acute gastro-enteritis and in 95 out of 244 cases of acute dyspepsia and symptomatic diarrhoea. Several pathogenic bacteria—paratyphoid, paratyphoid, and, in one case, typhoid bacilli—were isolated, and Bloch concludes that acute gastro-enteritis in infancy is due to infection, but not to any specific infection.

During the war a large amount of work was done upon intestinal infections in the many military laboratories in Europe and elsewhere. Our knowledge of the pathogenic bacteria, particularly of those causally connected or associated with intestinal disorders, has hereby been considerably increased. For example, the dysentery group of bacilli received a large share of attention, and in consequence these organisms have been more thoroughly differentiated. We are particularly indebted to Andrewes and Inman for a clarification of our knowledge of the Flexner group of dysentery organisms. On the other hand, the investigations carried out during the war brought to light many more connecting links between the well established bacilli, to which such names, for example, as "para-Shiga, indole-positive" and "para-Shiga, indole-negative" have been given. C. J. Martin and others have drawn attention to the fact that the organisms of the Flexner group are very variable in their properties.

#### PERSONAL OBSERVATIONS.

The summer of 1921 was very hot and dry, and one would have expected summer diarrhoea to have been very prevalent that year. Owing to the absence of some unknown factor or factors, we did not experience a severe epidemic, nevertheless a considerable number of typical cases did occur. My colleague Dr. Donald Paterson and I investigated 150 cases of summer diarrhoea and other conditions in which diarrhoea was a symptom among patients at the Hospital for Sick Children, Great Ormond Street. Unfortunately the labour entailed in making complete pathological and bacteriological investigations upon such a large volume of material proved too much for the assistance at our disposal, so that the bacteriological investigations we were able to carry out were not as complete as could be desired. Nevertheless, some interesting results were obtained.

The 150 cases studied were made up as follows: 111 cases of summer diarrhoea, of which 84 were fatal and 27 recovered; 36 cases of other diseases in which diarrhoea was a symptom; and 3 cases of nurses with diarrhoea. Bacteriological examinations were made (either during life or after death or both) upon 41 of the 84 fatal cases of summer diarrhoea, and upon the remaining 66 cases of the series—making 107 cases in all which were studied bacteriologically. Dr. Paterson has already described the clinical and pathological aspects in detail in a paper which was published in the *Lancet* (1922, vol. ii, p. 320). A few points brought out in that paper are worth recalling. The evidence of infectivity in our series of cases is slight. Of the 24 fatal cases, 45 were attacked when in a healthy

both may become in the course of time about equally deaf. I have only seen four cases (out of 41), I may say, in which the deafness was confined solely to the one ear. But the process seems to be self-limiting; for as time goes on the crises become less and less severe, until finally they disappear altogether, leaving the patient more or less deaf, but not stone-deaf. This variety is obviously very different in nature from the apoplectic type.

Now, as I have already pointed out, the recurrent labyrinthine storm may arise from a variety of lesions situated in a variety of places, so that to regard this, the ordinary type of the malady, as a disease entity having a precise pathological meaning would seem to be flying in the face of common sense. Yet, as a clinical picture, to my eye at least, it has the look of a definite disease, at all events when middle-ear trouble can be excluded. But what the nature of the lesion may be in this mild variety we do not know. Here again we stand in need of reliable pathological data. Meantime, is it permissible to hazard a guess as to its nature? Allow me to postpone my answer to that question. This type is certainly in most cases benefited, and indeed it is often promptly cured, by medicinal treatment. Potassium iodide has a well merited reputation for modifying and even stopping the attacks. And I have sometimes found a combination of nux vomica and potassium bromide (gr. x) equally efficacious.

There is, however, yet another, a third group—that namely, in which the attacks occur very frequently, often being induced by slight causes, such as a change in body position, and in which no tendency to spontaneous improvement is manifest, as time passes. Moreover, in this variety medicinal treatment is of no value. Naturally, this is a state of matters which may entirely incapacitate a patient from following his occupation. As to the pathology of this particular type, much has been conjectured, but little really is known. It differs, however, from the first two groups I have specified, chiefly in the frequency of its attacks, a feature which suggests that the canalicular system is in a continual state of hypersensitiveness. The deafness, moreover, is more severe than in the second group.

We may suppose, indeed, as Spear did some thirty years ago, that we have here to do with a rise in intralabyrinthine pressure, analogous to the elevation in intracranial pressure of glaucoma. Under the influence of this idea severe, frequently recurring, and obstinate vertigo has lately been treated by "uncapping" the external semicircular canal (suggested by Cheate and carried out by G. J. Jenkins), or more radical procedures (Hugh Jones, R. Lake, W. H. Mason).

Some have found vertiginous attacks (type unspecified) associated with a high blood pressure, while others, like Albert Gray, are of opinion that they are more frequently associated with an abnormally low blood pressure. At all events, some cases, as we have seen, are cured by potassium iodide, others by gruitin.

Finally, on one occasion I found the attacks and their effects wholly evanescent. The patient, a young woman, recovered not only from the vertiginous attacks, but also from the deafness. When last I saw her the hearing was normal. Moreover, I formed the opinion that in her case the recovery took place spontaneously, as she had many remedies during the course of her illness without any apparent benefit.

In concluding this section of our review I must once again emphasize the need for thorough pathological investigation in order that we may be delivered from the darkness and confusion that envelop us. Vertigo is only a symptom. The Meniere syndrome is only a group of symptoms, induced as acute septic labyrinthitis proves to us, by some sudden change in the vestibular system. What are the causes of this change in non-purulent cases?

Labyrinthine deafness from noise claims our attention next, chiefly because with the ever-increasing use of loud machinery in modern life it is becoming more common. Welcome efforts, however, are now being initiated to reduce industrial noises and their attendant industrial fatigue. They deserve our hearty support. Noise deafness, as Wittmach's experiments indicate, is due to degeneration of Corti's organ from over-stimulation, and Ritchie Rodger

has shown that, in the early stages at all events, the deafness corresponds with the pitch of the causative noise. A question here suggests itself. Is there any reason to suppose that the ordinary noises of modern life—the din of trains, tubes, motor buses, motor cars and cycles—induce a degree of nerve deafness in sensitive individuals of the general population? Another question I should like to ask. Does the deafness induced by loud noise progress after the exposure to noise has come to an end, or does it remain stationary? My own observations are too limited to allow me to form an opinion on this point. So far as I have observed, however, the deafness seems to remain stationary if exposure to noise is avoided. But I have sometimes noticed that these people become very deaf when they get old. It is as if the noise deafness led to an unusually severe senile deafness. But I should like to hear the views of others on this matter.

Senile deafness requires no particular description. But here also are one or two points worthy of attention. One is the peculiar absolute deafness caused by impacted cerumen in the meatuses of people suffering from mild senile deafness. This I have twice observed. On the removal of the wax hearing was at once re-established—that is to say, the patient was able to hear, although by reason of the senile deafness not so well as a normal person. This looks like functional deafness again.

As we get older the upper tone limit is lowered. Normally this seems to set in between 50 and 60, and the defect may be regarded as physiological unless the hearing for speech is impaired. Inasmuch, however, as we come across people who are prematurely aged, so also we may get early senile deafness. Not only so, but just as there is what we may call a regional sensitivity, such as the uniformly blanching of the hair, the early arcus senilis, and the like, so also may it not be that some cases of nerve deafness, coming on without any apparent cause in comparatively young people, are due to premature regional sensitivity of the cochlea?

Moreover, the increasing deafness that attends upon chronic middle-ear deafness after middle life is also probably due to senile changes in the labyrinth. Perhaps the functional deafness we have so often hinted at even times in an early atrophy of Corti's organ from disuse. On the other hand, the close pathological partnership between the middle ear and the labyrinth is noticable even in senile deafness, which is due not solely to cochlear change but also to an insidious thickening of the tympanic membrane with stiffening of the ossicular articulations.

Now there is an insidious form of nerve deafness, known as progressive nerve deafness, which appears without any signs of labyrinth or canalicular irritation, without other vertigo or tinnitus. It is a silent deafness. Unfortunately, in this connection as elsewhere we have to report much discrepancy in the pathological evidence. Some have observed a general degeneration of the auditory nerve system, starting at the auditory "nerve root" and extending peripherally to involve the organ of Corti. Others see the process beginning and ending in the ductus cochlearis. Clinically also the voices are not in accord. Manasse states that it occurs chiefly in old men. The term "progressive" implies that it is a disease which marches steadily on to its end, which is the total destruction of the sense organ and complete deafness; yet Selligmann says it sometimes comes to a standstill. Finally, Manasse mentions as its possible causes arterio-sclerosis, syphilis, chronic nephritis, and middle-ear inflammation, all of which, I may add, are diseases either induced or induced by senility, general or regional.

In other words, I suggest that this progressive nerve deafness is simply a senile change which may appear unilaterally. And my suggestion is favoured by the fact that the changes induced by senility resemble those we have described, consisting as they do of an atrophy, this time of the auditory nerve endings. At the same time one would be careful not to proceed beyond suggestion at the moment. Here, as elsewhere, we require more, much more, pathological information than we at present possess before our opinions are worth making, much less listening to.

We pass now to syphilis of the labyrinth, of the anatomical changes of which, said Politzer in 1899, "but little is known."

condition, and in 39 there was a history of previous digestive troubles; we call these cases "acute" and "chronic" respectively. The theory that the infection is conveyed in the milk did not receive much support from this series of cases. The curve of onset shows two maxima, one about the third to fourth week in July, and the other about the first week in September, as though there were two epidemics, as suggested by Brownlee.

In the "acute" cases there was usually a history of sudden vomiting and diarrhoea—the motions were green, slimy, and only rarely contained blood. On only one occasion was pus detected in the stools. In the "chronic" cases there were many watery, green, slimy, undigested stools which very rarely contained blood. The patients rapidly passed from the stage of "dehydration" to one of "intoxication," then became comatose and died. *Post mortem* the most important as well as the commonest lesion was a varying, and at times an extensive, degree of fatty change in the liver. The kidneys were similarly affected, but to a less extent. The intestinal lesions varied considerably in degree. At times the intestines appeared quite normal, at others there was a catarrhal enteritis and colitis with excess of mucus. Some cases showed definite ulcer formation, either small punched-out ulcers, or larger, shallow, irregular ulcers. The changes were more marked in the big bowel and particularly in the neighbourhood of the caecum; they included congestion, petechial haemorrhages, follicular ulceration, general thickening and induration or ulceration, and occasionally a definite membranous colitis.

The results of the bacteriological investigations are set out in the accompanying table. In it we see that no non-

by previous observers and labelled a "non-agglutinable dysentery bacillus."

As has been recorded so often by other investigators in the case of different organisms, so I have found to be the case here—namely, that the properties of the bacillus have changed after frequent subcultures. For example, several of the strains which in 1921 produced indole, now fail to do so, and one which did not form indole on isolation now does so. One strain forms acid in lactose on the first day, whereas in 1921 no acid was observed until the sixth day. On isolation the agglutination reactions with a dysentery Flexner-Y serum were kindly tested for me by Drs. Ledingham and Brooks of the Lister Institute. The results were all negative except in the case of one strain which agglutinated at 1 in 100 (it was not tested in higher dilution). I have since carried out a large number of agglutination reactions (which are, however, not yet completed) and have found hitherto that the only heterologous serums which agglutinate this group of bacilli are those of *B. coli communis* and the "Newport" and "Mutton" strains of *B. suipestifer*.

A few feeding experiments recently carried out on young rabbits have resulted in producing diarrhoea and death in some of the animals, from the heart blood of which I have succeeded in recovering the bacillus. This organism or group of organisms has not received much attention from bacteriologists. Alexander, in the reports already referred to (1911 and 1912), states that in 1911 he encountered them frequently, and in 1912 he paid particular attention to them. He isolated them from 7 out of 100 normal children and from 9 out of 77 diarrhoea cases. He describes 11 different varieties from his diarrhoea cases which produced acid and no gas in lactose, but only one which produced no gas in any sugar medium. From the normal children he isolated 5 different varieties, 3 of which produced no gas in any sugar. Fifty-nine strains were tested by feeding to young rabbits: 8 proved to be pathogenic—2 out of 8 obtained from normal children, 3 out of 26 from diarrhoea children, and 3 out of 25 obtained from other sources. He gives in his paper a list of the previously investigated acid producers: several were isolated and named by Castellani; others were isolated by Dr. Cox from flies in insanitary areas in Liverpool during the summer of 1911; others again were isolated by Gettings from cases of pseudo-dysentery at Wakefield. I had myself isolated it from a patient with clinical dysentery at the Wakefield Asylum early in 1912, and quite recently I have isolated a strain from a long-standing case of bacillaria.

Bainbridge, in his paper "On the paratyphoid and food-poisoning bacilli," 1909, describes a strain of *B. suipestifer* which never formed gas in any medium, and mentions that a similar strain of *B. suipestifer* was described by Bock in 1906.

Coming back to our table, it is interesting to note that the *B. dysenteriae* was isolated from as many as 13 cases out of 107. I have no doubt, from my eleven years' experience at Great Ormond Street, that infections due to the *B. dysenteriae* have been much more commonly met with in children since the war began than in the pre-war days. This is what one would expect from the large number of men who suffered from the disease, some of whom are no doubt carriers. The cases from which *B. typhosus* was isolated constituted a small group of 5 children and 2 nurses, who contracted the disease from a known source. The organisms I have called paratyphoid B type, indole positive or negative, are probably harmless intestinal organisms for which Savage has suggested the name of "para-Gaertner bacilli." Lastly, one must draw attention to the fact that Morgan's No. 1 bacillus was not isolated from a single case in 1921, though in previous years I had come across it in the children at Great Ormond Street, and in 1911 I isolated it eight times in association with other bacilli from about 50 cases of asylum dysentery at Wakefield.

In 1922 extensive preparations were made at the Great Ormond Street Hospital, under the auspices of the Medical Research Council, for a full investigation of summer diarrhoea, but unfortunately for the investigation very few cases of the disease occurred. While waiting for cases Dr. Marshall Findlay investigated the bacteriology of the stools

Analysis of Diarrhoea Cases Investigated (1921).

Organisms Isolated.	Fatal Cases of Summer Diarrhoea.		Non-fatal Cases of Summer Diarrhoea.	"Other" Cases of Diarrhoea.	Mixed (Two or more clinical types).	Totals.
	Acute.*	Chronic.				
No. of cases examined	22	19	27	36	3	107
<i>B. coli anaerogenes</i> ...	7	4	10	2	2	25
<i>B. dysenteriae</i> ...	2	1	3	7	0	13
<i>B. typhosus</i> ...	0	0	0	5	0	5
<i>B. paratyphosus</i> B-type, indole-negative	1	1	0	0	0	2
<i>B. paratyphosus</i> B-type, indole-positive	2	2	0	3	0	7
<i>B. proteus vulgaris</i> ...	0	2	0	4	0	6
Non-lactose fermenters isolated	14	9	14	19	1	57

\* These cases were examined bacteriologically and *post mortem*, and are referred to in the paper by Dr. Paterson, with short bacteriological report by Dr. Vabarro (*Lancet*, 1922, ii, p. 320).

† Acute = apparently healthy children suddenly attacked by diarrhoea. Chronic = children with history of previous indigestion, diarrhoea, and failure to gain weight.

‡ These include cases occurring during summer and all cases of diarrhoea (including "D. and V.") occurring out of the season.

lactose fermenters were isolated in 57 of the 107 cases investigated. No doubt we missed these organisms in a certain number of the cases owing to the want of sufficient assistance to enable us to make repeat examinations of the faeces in the negative cases. The organism most frequently isolated (25 times out of 107 cases) was one which produced acid but no gas in the sugar and alcohol media used—glucose, mannite, lactose, saccharose, and maltose. It was generally non-motile, was Gram-negative and a non-liquefier of gelatin, formed acid and generally a clot in milk, and only rarely formed indole. It closely resembles, if it is not identical with, the *B. coli anaerogenes*, first isolated from the faeces of dogs, and described by Lembke in 1896. Several strains of the organism were met with in our cases. They all formed acid in glucose and mannite in one day; saccharose and maltose were acidified by some and not by others. In lactose acid was usually produced in one to three days, but sometimes not until the ninth day, and occasionally not at all. This variety, which apparently formed no acid in lactose, might quite well have been found

and the agglutinating properties of the serums of normal children chosen from the out-patient department of the hospital and from welfare centres. He has kindly furnished me with the following summary of his results: 304 investigations of the faeces or rectal swabs were made from 139 cases; in 13 cases organisms of the dysentery group were isolated, in only one of these, however, did the child's serum agglutinate the organism isolated; in 115 cases of normal children the agglutinating power of the serum was tested against *B. dysenteriae* Flexner, *B. enteritidis* Gaertner, *B. aertrycke* ("Mutton"), and Morgan's bacillus No. 1; 13 agglutinated *B. dysenteriae*, but never higher than 1 in 50, 3 the *B. enteritidis*, and 1 *B. aertrycke*. In the 6 cases of summer diarrhoea studied, a specific *B. enteritidis* infection was found once, giving both a positive culture and agglutination.

#### CRITICAL REVIEW.

The one outstanding fact which emerges from the foregoing review of the bacteriology of summer diarrhoea is that in different outbreaks of the disease many different organisms have been isolated by the same observer or group of observers, and that at the same time one particular organism, be it a dysentery bacillus, a *B. proteus*, a Morgan's bacillus, or a *B. coli anaerogenes*, has been the organism most frequently met with. This suggests the first question we must endeavour to answer—namely, Is summer diarrhoea a single clinical entity like typhoid fever, or are there several diseases included under that heading? Certainly in some epidemics—for example, in America—the type of the disease has been more severe and more like clinical dysentery than has been the case in our English epidemics. But in our own cases we have found lesions of all grades of severity *post mortem*, yet clinically the types of the disease had been very similar. I believe myself that the disease is one and the same all the world over, and not an infectious disease in the strict sense of the term, but rather of a metabolic origin with a secondary infection by one of a number of different micro-organisms, which have for the time being, in a manner I shall suggest later on, become either more virulent than usual or pathogenic after being non-virulent. The diarrhoea and vomiting I regard as symptoms of that metabolic disturbance, and the consequent "dehydration" and "intoxication" as secondary effects of the loss of water from the system. This in turn gives rise to reduced elimination of toxic substances by the kidneys, reduced action of the liver owing to its fatty degeneration, and so a "vicious circle" is established.

There is no doubt that the Americans isolated dysentery bacilli from 63 per cent. of their cases, also that Morgan and Ledingham isolated Morgan's bacillus from 63 per cent. of their "selected" cases, but this does not prove that either organism is the actual cause of the disease. The French investigators isolated *B. proteus* from nearly all their cases, and in 1921 I failed to find Morgan's bacillus even in one case. Certainly in any one year or series of years one particular organism may be the predominant one, but it must be remembered that all observers have found many other forms, some allied to the dominant bacillus, others more remotely resembling it, if at all. I emphasize this point because it leads to the vexed and important question of bacterial instability and metamorphosis.

The essence of life is growth, change, and evolution. Presumably bacterial life dates from the Creation, but it is less than fifty years since it has been studied scientifically by modern methods. We know that bacteria grow and therefore may change and undergo evolution. A month or a year in the life of a micro-organism and its progeny may be equivalent to a thousand years in the case of man and the higher animals. As with the higher forms of life, bacteria undoubtedly respond to and are affected by changes in their environment—for example, heat and cold, diet, and, in the case of intestinal bacteria, the reaction and composition of the intestinal contents, other organisms (symbiosis), the presence of bacteriophages, and so forth. Possibly, too, bacteria may have their own diseases; they certainly have their enemies as well as their friends. There are undoubted signs that bacteria are changing their characteristics. Hiss, Neisser, Rodet, Massini, Twort, and

Penfold have given instances of this in their writings on bacterial variation. A host of investigators have remarked that in studying the bacteria isolated from cases of diarrhoea and dysentery many different strains of bacilli have been present; either the sugar reactions varied, or their behaviour in milk, or their power of forming indole, and even their agglutinability.

Furthermore, it has been noted very frequently that under our very eyes, during a period of even a few months only, one or more of these properties of a particular organism may vary on subculture. If that is so, surely it is not too great a stretch of the imagination to ask you to believe that these very same changes may be going on in the intestine of the host in whom a bacillus may have effected a temporary or permanent lodgement? Take, for example, Morgan's No. 1 bacillus. Morgan himself says that Houston and MacConkey, both of whom are careful observers and had examined hundreds of strains of bacteria from sewage, waters, milk, etc., had never come across his No. 1 bacillus. All these observers used the same methods of investigation, and it is unlikely that it was overlooked by Houston and MacConkey—therefore it must be an "entirely new organism." I think this very improbable, and that it is much more likely to have been evolved from some other bacillus. Morgan says it is most like the bacillus of hog cholera; it is obviously not far removed from the Shiga bacillus. It is interesting to note that several observers (Bainbridge, Bock, Ten Broeck, Savago and Forbes) have recorded strains of *B. suipestifer* which have lost the property of forming gas from glucose and other sugars. It will be remembered that my strains of *B. coli anaerogenes* agglutinated with *B. suipestifer* serums. Perhaps the explanation is that the fashionable diarrhoea bacillus which in 1905-12 was the Morgan No. 1, in 1921 appeared in the form of *B. coli anaerogenes*, and by 1930 will have changed to something apparently different.

What evidence is there that these organisms, which are admittedly present in a large percentage of the cases of summer diarrhoea, are the actual causal agent? There is evidence both for and against this view. In favour of it we have their frequent occurrence in cases of the disease and the fact that the blood of the patients often agglutinates the bacillus, though frequently not in high dilution. Against this view is the fact that the same organism may be isolated from normal children and from flies in infected houses. During epidemic seasons the non-lactose fermenters have been isolated more frequently than in non-epidemic seasons. This is to be expected. During an epidemic the chances of direct infection, the infection of milk and other foods, either by the hands of mothers, or by soiled cloths, or by flies gaining access, are naturally greater than at non-epidemic times, especially if due provision is not made for immediate disinfection or disposal of the excreta or soiled napkins. The pathogenicity or otherwise of the isolated microbes for the lower animals also proves little, for (1) diarrhoea-producing and even fatal strains of Morgan's No. 1 bacillus and *B. coli anaerogenes* have been isolated from normal children, and (2) many strains from diarrhoea cases have not been pathogenic to animals by feeding.

While admitting, therefore, that these organisms may play a part in summer diarrhoea, I do not think they are the sole or even the principal exciting cause. I am inclined to agree with the dictum of Pfaunder, quoted by Liefmann, that in summer diarrhoea children sickened *ex alimentatione*, and that they died *ex infectione*.

If we admit (and much evidence in favour has been adduced) that most, if not all, of these bacteria may be harmless intestinal inhabitants, what conditions determine their conversion into harmful pathogenic agents? These I can give only very briefly as follows:

#### A. Diminished Resistance of the Individual.

1. General—from exposure to great and prolonged heat, undue and prolonged exposure to cold (Gettings found that many patients developed dysentery at Wakefield Asylum during the coal strike in 1912), malnutrition from underfeeding, improper feeding, and perhaps vitamins A and B underfeeding (Cramer).

2. Local—that is, in the alimentary canal.  
(a) Diminished acidity of the gastric juice allowing more swallowed bacilli to pass into the intestine.

DISCUSSION.

Mr. W. M. Morsos (London) agreed as to the difficulty in distinguishing, by hearing tests, between conductive and nerve deafness. He divided deafness into qualitative and quantitative. The qualitative group included those with lower tone loss and upper tone loss, while the quantitative group included cases where the tones were normal but there was general diminution. Some of these were familial, some toxic—due, for example, to influenza, mumps, or tonsillitis; he had seen one case of mumps with vertigo. He mentioned Fink's point of the relation between Page's disease and nerve deafness, and gave notes of a case. Mr. Morrison then dwelt upon the importance of loss of the upper tone limit, and the use of the monochord in comparing air and bone conduction. In syphilis a helpful sign was diminution of the upper tone limit through bone. He called attention to the acute hearing of the blind and of certain types of war neurotics, who could hear a whisper for long distances. He also spoke of the extraordinary sensibility to cold and pressure of the vestibules of some of the latter patients. Were the semicircular canals, he asked, becoming less valuable to man? He suggested that perhaps these neurotics were not able to exclude useless stimuli as other people had to learn to do.

Mr. A. J. Waring (Bristol) said that every case of vertigo was not in need of middle-ear treatment. It might be the patient's attention on his symptoms. In regard to mumps, in an epidemic he had found that in two cases of deafness, if the noise was removed the deafness did not as a rule progress. He classified 71 cases from the point of view of etiology, dividing them first into two groups—those with an obvious cause, such as trauma or syphilis, and those with a doubtful cause. There were 31 males and 40 females; excluding those cases caused by trauma and noise, the condition was present in women much more frequently than in men. In the war cases there were many pre-existing middle-ear disease. Of the doubtful cases, the foot seemed to be the cause in four, the foot being in the teeth or tonsils. Functional cases were six in number, and had begun with some suggestion, such as a syringing the ear. Of the other cases most were found in association with vasomotor rhinitis, chills, and thyroid deficiency.

Sir JAMES DUNN-GRAVE (London) said that in semio-vertigo "semio" did not mean old age but old arteries. Considerations, the safety valves, the fenestrae, being prevented from acting by adhesions. Quinine was of value in unilateral labyrinthine vertigo, given in half-grain doses, the explanation of the benefit being that it caused a diminution of sensitivity of the sound ear. Loss of upper coats limit meant a lesion in the cochlea. The tuning-forks were open to fallacies. He raised the point of whether diseased middle-ear cases as seen in the war really predisposed to labyrinth trouble. Certainly mastoid destruction predisposed, mechanically. He suggested that Dr. Mollison called "quantitative" deafness was due to an exhaustion of the auditory centres, not uncommon in neurasthenia. Tramaatism had often produced an increase of chronic labyrinthine trouble, and mercuric chloride was of benefit in these cases.

Dr. W. J. Litchton (Manchester) said that syphilis in a case was somewhat neglected; syphilis insensitum was a thing not to be missed. He quoted a case which occurred in a surgeon who contracted the infection during an operation upon a varicose ulcer. The psychological factor was of importance. He had seen a labyrinthine storm, in a case of Eustachian obstruction, relieved by induction. He emphasized the importance of the otologic test, in distinguishing between central and labyrinthine trouble. The President said that the discussion had brought out the important points that in a considerable proportion of cases of internal ear deafness, evidence of infection of

We have touched upon mumps deafness, noise deafness, syphilitic deafness, hepatic deafness, and we have suggested that a large, class of labyrinthine deafness is due to middle-ear diseases. Now, however, it is necessary to trace what is after all our central problem. Even including labyrinthine deafness secondary to middle-ear disease or produced by those causes to which we have alluded, how relatively seldom it is that we are able to surmise, even vaguely, what the cause of their trouble may be in patients who come to us with nerve deafness! Out of 345 cases in my own private practice I find that in 129, or 36.5 per cent., the cause remained unknown. And as the cause is hidden so it comes about that our treatment is purely haphazard. To some we give nuxvomica, to others potassium iodide, to all our sympathy. And there the matter ends.

But must we always be standing in deep resignation before this problem? Have we really done all that we can to solve it? Let us see.

For the last few years we have been working on the removal of the retino-cycloids and the removal of the retino-cycloids. In many of these cases the removal of such foci seems to exercise little or no influence upon the ocular trouble, yet every now and then a brilliant result rewards our efforts. It is not possible to point out in the laboratory also lesions due to a remote septic focus may occur. This question particularly regarding the group of the labyrinth storm cases to which I alluded in an earlier section. Many of these cases can be explained, it seems to me, in this way. Some of them are "gouty", others, as in a case reported by Spalding, may even manifest ocular lesions. There is a question that ought to be answered, perhaps it will be answered to-day. In any case such a problem can only be tackled in one way—namely, by the method of removal of such foci from patients with deafness for which no other cause can be found. A prolonged and widespread experimental therapy is, in fact, called for. It may, after all, come to nothing. But it is certainly worthy of trial, and for the living patient, for this is one of the problems no more pathological inquiry could solve.

as we look back now upon this section of ladywith deaf-  
factory feature of a picture by no means wanting in shadow  
And however great progress may be in the future, it will  
always be true, I fear, that treatment will remain unsatis-  
factory. Nothing can restore a destroyed sensory end-  
organ. Nothing can rejuvenate an organ of Corti rendered  
useless by age and disease.  
Yet we are not without hope. For although we cannot

[illegible]

(b) Irritation of the bowel by chemical "poisons" in milk or other food, or made locally—for example, tryptophane and other protein degradation products.

(c) Reduction in the numbers of the beneficent intestinal microbes, particularly the anaerobic acidophile or "acid-tolerant" bacilli which normally check the overgrowth of *B. coli* and allied forms. Possibly bacteriophages play a part in this process.

(d) Stunting and atrophy of the intestinal villi consequent upon underfeeding with fat-soluble vitamin A, whereby organisms are enabled to multiply enormously in the mucous glands of the caecum, as Cramer has recently shown.

(e) Increased formation of harmful acids as by *B. coli* and *B. welchii* leading to increased peristalsis and diarrhoea and a catarrhal or inflammatory condition of the bowel wall (Distaso).

#### B. Increased Virulence of the Bacillus.

1. "Mass action," whereby is meant the ingestion with the food of greatly increased numbers of the organism, which has multiplied owing to the temperature. The local overgrowth in the intestine just referred to would act similarly.

2. Increase of toxicity on account of passage through a former patient.

3. Symbiosis—for example, through association with *B. proteus* or other intestinal organism, possibly a filter-passing virus.

Two or more of these conditions may act together and I cannot help thinking that the primary cause of summer diarrhoea is to be found under this heading rather than in any one particular micro-organism.

In conclusion, I should like to convey my thanks to my assistant, Mr. Stanley Woodward, whose valuable help has enabled me to carry out all the work referred to in this paper.

#### DISCUSSION.

Dr. DONALD PATERSON (London) said that of the vast group of cases which suffered from diarrhoea in summer time, only a comparatively small proportion were severe enough to become in-patients at a hospital. Of the cases admitted to hospital possibly one-half to three-fourths died, depending on the length of their illness before admission and the gravity of their condition on admission. Of those cases which died and came to *post-mortem* examination, less than one-half showed any pathological lesion in the bowel wall, and from even those which did show ulcers or erosions of the mucous membrane an organism pathogenic to man could be obtained in only a small proportion of cases. Blood and mucus in the stools of cases of summer diarrhoea was an extreme rarity in this country and was taken in America as the criterion on which to diagnose clinically between an infective and a so-called fermentative diarrhoea. In more than one-half of the fatal cases of summer diarrhoea, therefore, there was no pathological or bacteriological evidence of infection by an organism pathogenic to man. It might safely be assumed that of the vast number of cases that recovered the majority had not been infected by an organism pathogenic to man. They had not been suffering from an ileo-colitis, for it was noted constantly in hospital that this type of case was uniformly fatal. The question then arose, what was the cause of the diarrhoea in those children who succumbed showing no pathological lesion in the bowel or other organs, and in those children who had completely recovered from their attack of diarrhoea? This group comprised by far the greatest proportion of the whole of the cases of diarrhoea in summer time. An analysis of the case-histories, especially from the feeding standpoint, would lead one to believe that in this direction lay the main fault. At least one-half of all these cases had a history of unsatisfactory feeding and mismanagement. Prior to the onset of their illness they were suffering from malnutrition or marasmus; their stools were loose and contained partially digested food elements even in cold weather. On the advent of warm weather this condition of indigestion was exaggerated merely, and they passed into a state which was indistinguishable clinically from a case of true infective diarrhoea. The other half of this group were as a rule at the other extreme as regards nutrition. They comprised the fat, overfed infants who were putting on weight rapidly and whose digestive organs were being pushed to the extreme limit to handle the food offered them. With hot weather those children developed an acute attack of dyspepsia which manifested itself by diarrhoea and vomiting—nature rebelling against too much food. This might occur on artificial food or even on breast milk. Starvation in an infant of that type was badly borne and quite quickly it developed the condition known as "acidosis." In these cases *post-mortem* examination revealed only an extreme fatty change in the liver. This group, in which there was no pathological or bacteriological evidence of infection by an organism pathogenic to man, had been termed "fermentative diarrhoea," or diarrhoea due to "auto-infection." Whether they were really suffering from auto-infection by the normal organisms of the bowel or whether their condition was due to an exaggeration of the fermentative action of the bowel organisms during the warm weather was difficult to prove. Certainly a diet which tended to reduce fermentation in the bowel seemed to suit them better than any other which he had found. In Dr. Paterson's opinion the large proportion of cases of diarrhoea in this country were due to a primary dietetic error, which was easily produced in hot weather and owing to the tendency for children to be overfed. Possibly increased fermentation of the carbohydrate portion of the diet due to an overgrowth of the bowel organisms took place and exaggerated this dyspepsia. The main proof of that rested on the beneficial effect of a diet in which fermentation was reduced to a minimum.

The PRESIDENT (Dr. Edmund Cautley) said that Dr. Nabarro had raised many interesting points. It was especially interesting to hear that he did not consider summer diarrhoea as infective. But if Dr. Nabarro

The relations of the optic nerve to the sphenoidal and posterior ethmoidal cells of the nose are similar to that of the facial nerve and the middle ear, and it appears to me that this analogy can be carried further in the cases of retrobulbar neuritis. Paralysis of the facial nerve as the result of ear disease is most commonly due to the chronic and more destructive suppurative seen in tuberculosis of the middle-ear cleft, and I believe it is the more destructive chronic suppurative of the nose which produces retrobulbar neuritis. Professor Onodi, in his book *The Optic Nerve and the Accessory Sinuses of the Nose*, gives the pathological details of nine cases recorded by different observers in which optic neuritis was due to sphenoidal and ethmoidal suppuration with peristitis, osteitis, and necrosis, and confirmed by *post-mortem* examinations. The disease was extensive and destructive, and accompanied by meningitis, extradural abscess, or venous thrombosis. The optic nerve was affected by direct extension from the bone, or more rarely by venous thrombosis. It is only in a very few of the many cases of suppuration of the sphenoid and ethmoid that the optic nerves are

[illegible]

## DISCUSSION ON RETROBILBAR NERVIUS OF NASAL ORIGIN.

There is also the question of the resistance of the organs. Some organs are no doubt more resistant to infection than others, and it would appear as if the bronchial glands are less resistant than the abdominal glands, which drain the intestines.

#### *The Progress.*

In judging the outlook of this disease we need to look not at the results as seen at the end of a course of treatment, but at the results as seen many years later. Cases are often thought to be cured after treatment, but when we come to investigate these cases some years later we find that the mortality is a good deal higher than we anticipated at first. We need to be more cautious about calling a case cured too soon. This is well shown by this series of cases, and the outlook in many cases has turned out to be a good deal worse than was thought at the time of ending treatment.

A case of abdominal tuberculosis should remain free from symptoms for at least two years before being pronounced as cured. Practically all the cases that I have watched, if they have kept free from symptoms for two years, have almost invariably done well.

During the first year of life the outlook is practically hopeless, and it is not very much better during the second year of life. The disease is specially difficult to diagnose at an early stage at these ages, and it is possible that there are mild cases which are not recognized and which recover.

I have seen eleven cases under the age of a year, most of them between the ninth and twelfth months, and all of these have died, nearly all from a general tuberculosis. An interesting feature of these cases is that there is a family history of tuberculosis in a near relative in a high percentage of cases. In quite a number also the infants had had no unboiled milk in their lives. It would thus seem that a large proportion are due to the human type of tubercle bacillus.

Looking at the older children, the outlook improves very considerably, although the disease is always a serious one, and one needing prolonged treatment and care. Many cases relapse or develop tuberculosis in some other part of the body later on. The more that one can feel in the abdomen in the way of glands, matted omentum, etc., the worse is the outlook, yet it is remarkable what large masses can disappear in time under treatment. The type of case which has ascites does better on the whole than the plastic or adhesive type. Of my cases with ascites 23 have had a laparotomy performed, and 15 of these are living and well, showing 65 per cent. of permanent recoveries. Thus, many cases of the ascitic variety do well after an operation for the removal of the fluid, but why this should be so is doubtful. After all, the ascitic is turned into one of the plastic variety. This apparent relief by laparotomy is, however, sometimes only temporary, and after a few weeks they take on the symptoms of the plastic type with pain and obstruction.

In so-called *tabes mesenterica* an abscess may form, and this is generally best left to open at the umbilicus and discharge, in the hope that it will dry up and heal without a faecal fistula. There is always a great risk of a faecal fistula if the plastic variety of abdominal tuberculosis is operated upon.

When we come to analyse the series of 250 cases of all ages, we may sum up the results as follows:

Cured	...	...	...	...	...	...	56 per cent.
Doubtful	...	...	...	...	...	...	8 "
Death, or outlook very bad	...	...	...	...	...	...	36 "

If we exclude the 11 fatal cases which occurred in the first year of life the table is better, and shows:

Cured	...	...	...	...	...	...	53 per cent.
Doubtful	...	...	...	...	...	...	8 "
Death, or outlook bad	...	...	...	...	...	...	31 "

Taking the results of children over 5 years of age when first seen, the outlook is shown to be better still—namely:

Cured	...	...	...	...	...	...	62 per cent.
Doubtful	...	...	...	...	...	...	6 "
Death, or outlook bad	...	...	...	...	...	...	32 "

These statistics go to show how serious the disease is in children; in fact, the outlook for abdominal tuberculosis is much worse than the outlook in chest tuberculosis of children. It would appear that when the mesenteric glands

and peritoneum become seriously affected, the body resistance to the disease is small. This would be expected when one comes to consider the large surfaces and organs involved.

When we go into the after-histories of cases who have recovered we find that the large majority have grown up and kept perfectly well. They have no symptoms of the former disease, except that a few have a tendency to colic and to looseness of the bowels. The adhesions and matting of the intestines seem to have but little deleterious effect in the future. In some, however, a mass of calcified glands can be felt many years later in the same situation as the former enlarged glands. These old glands seem to cause no trouble. The earlier a case is treated by rest and suitable diet the better is the outlook.

It is likely that abdominal tuberculosis is a potent cause of sterility in females by causing adhesions and damaging the reproductive organs.

#### *Amount of the Dose.*

It is clear that infants and children have every chance of becoming infected with the tubercle bacillus at an early age. As the age of children increases we find that more and more have been infected, but that resistance to infection is such that they thrive in the ordinary way. It is possible that the magnitude of the dose and the continuance of infection has a good deal to do with an illness like abdominal or chest tuberculosis. A long series of doses of infection will most likely set the disease going, while a small dose or doses may be resisted by the child and all goes well, although he is infected. This is clearly shown by the bad outlook when there is a tuberculous parent, who is continually infecting his or her children by living in the same house and by not taking sufficient precautions.

#### *Summary.*

I have been able to follow up 250 cases of abdominal tuberculosis in childhood for a number of years, and the results have been analysed. Many cases are apparently cured for a time, but relapse later on; this point must always be borne in mind. The outlook is practically hopeless under the age of 1 year, and not much better under the age of 2 years. However, as the age increases the outlook improves considerably, although the disease is always a most anxious one. The more that can be felt in the abdomen, the worse as a rule is the outlook. The type with ascites does better on the whole than the other types, and this class of case often responds well to operative treatment. The after-histories of children who have had abdominal tuberculosis and kept well for some years are good, even though there are still enlarged calcareous glands felt in the abdomen.

#### DISCUSSION.

The President (Dr. EDMUND CAUTLEY) said that the prognosis in abdominal tuberculosis was not as bad as it used to be. With the advent of abdominal surgery the outlook became suddenly much better. Surgeons sometimes used to open the abdomen under a mistaken diagnosis. Tuberculous peritonitis was discovered and a hopeless prognosis given. Then it was found that many cases recovered. Laparotomy became the popular treatment, and various theories were suggested as to how it worked. The physicians thought that with suitable diet (and diagnosis) the prognosis was good. The outlook was worst in the caseous type unless the disease was localized. The after-effects were wasting, leading eventually to death, intestinal obstruction, and generalized tuberculosis.

Dr. E. A. COCKAYNE (London) commented on the absence of after-effects in the cases that recovered. He had felt calcified glands and nodules in the omentum years after the original disease, but they produced no symptoms.

Dr. ERIC PRITCHARD (London) agreed in the main with Dr. Ashby's conclusions, except on the point that tuberculosis in children under 1 year of age was specially fatal. Some years ago he himself had made this statement, but since then he had had reason to change his opinion. During the last ten years he had treated a number of children

involved, and in this respect again the relation of suppurative middle-ear suppurations and the facial nerve. In all these cases the cause of the neuritis was definitely due to gross and severe suppurations of the sphenoid and ethmoid, and though unilateral neuritis is considered to be more common and indicates a nasal origin, both nerves were sometimes affected, and it has been claimed that optic neuritis has been known to be due to sinus suppuration on the opposite side of the nose. For this and anatomical reasons, it is always advisable to open and drain the sphenoidal and posterior ethmoidal cells of both sides in cases of retrobulbar neuritis of nasal origin. It is true that acute otitis media occasionally produces facial paralysis, but there are a large number of cases of transient paralysis in which no cause can be found, and the paralysis disappears in a few weeks. In this respect facial paralysis resembles the 23 cases of idiopathic retrobulbar neuritis about to be discussed, the majority of which recovered.

The severity of the 23 cases of retrobulbar neuritis for which no cause could be determined showed that these were of sudden onset and usually occurred in women under 40 in whom the nose was perfectly normal, and repeated examinations with exploration of the sphenoidal sinuses and antra yielded a negative result. In 3 of these cases the middle turbinate was removed, the sphenoidal and ethmoidal sinuses were opened and found to be normal, and there was no improvement in the sight as the result of this procedure. In another case the nose was not above suspicion, and as there was no improvement, the sphenoid and ethmoid were opened and found to be absolutely normal. This case ultimately turned out to be disseminated sclerosis, in which the sight varied as in other cases due to the same cause.

In most of the 23 cases x-ray examination, Wassermann reaction, tests of urine and of the nervous system, and searches for tuberculous were all negative, neither was there any evidence of toxæmia, and though the patients were seen at intervals for more than twelve months no further information as to the etiology was obtained. Nevertheless the sight improved or became normal. It is possible that an examination of the cerebro-spinal fluid may have thrown some light on these cases, but unfortunately lumbar puncture was not done.

Bruckner records ten cases of unilateral retrobulbar neuritis in which the sphenoid and ethmoid were examined and no nasal lesion was found. Other observers, particularly in America, report that a much greater number of cases of retrobulbar neuritis are due to nasal disease, and it may be claimed that some of the above idiopathic cases have a latent nasal lesion which cannot be detected macroscopically.

If the severity of the symptoms in a case of retrobulbar neuritis is progressing and every other cause for suspicion of sphenoidal and ethmoidal disease, then it would be justifiable to remove the middle turbinate and open up the sphenoidal and ethmoidal cells; the risk of damage done by such procedure is negligible.

In conclusion, only 4 out of 54 cases of retrobulbar neuritis were produced by nasal suppuration, and in those 4 and in others recorded the suppuration and disease of the sphenoidal and ethmoidal cells was obvious and extensive. An improvement in the sight after the sphenoid and ethmoid have been opened and when little or no disease was found does not conclusively prove that the neuritis was caused by the nasal condition.

LITERATURE.

STICHT THOMSON: Optic Neuritis of Sphenoidal Sinus Origin. *British Medical Journal*, June 2nd, 1922, p. 955. Cerebral and Ophthalmic Complications in Sphenoidal Sinusitis. *Trans. Medical Society of London*, xxxi, 1926.

DISCUSSION.

SIR STICHT THOMSON (London) said that at present there was a "boom"—the second one in twenty years—in the relation between sinusitis and retrobulbar neuritis. He

FIG. 1.—Horizontal section of left maxillary antrum, showing "loose" to be opened in this operation.

CANFIELD'S OPERATION ON THE ANTRUM:

DESCRIPTION AND RESULTS.

SIR JAMES DUNDAS-GRANT, K.B.E., M.D., F.R.C.S.

When referring recently to some cases as having been treated for their chronic suppuration in the maxillary antrum by "Canfield's operation" I was asked by a distinguished laryngologist what I knew of Canfield's operation. I knew its acquaintance in Loebe's masterly *System of Operative Surgery of the Nose, Throat, and Ear*. It appeared to me to have such distinct and valuable features as to justify its being named after its putative discoverer. The main feature in it is that the opening is made in the narrow anterior part of the antrum, close to the margin of the pyramidal orifice of the skull. This margin can be distinctly felt by a finger pressed into the naso-facial fold externally, while if the nose is tilted up and the naris is opened by means of a nasal speculum, not pushed too far in, a corresponding fold running nearly vertically can be seen or felt. The anterior part of the antrum, which is narrow, comes forward towards the edge, though at some little distance posterior and external to it.

The antrum being exposed at this anterior part it is easy to look straight into it or introduce an irrigating cannula in a way that no other intranasal operation permits of. It is likely also that the position of the resulting opening, situated as it is at a narrow part of the nasal passage, allows of the production of negative pressure as the respiratory currents of air pass over it.

In Canfield's original paper (*Journal Amer. Med. Assoc.*, vol. li, p. 1136) the operation is described as "the submucous resection of the lateral nasal wall in chronic empyema of the antrum, ethmoid, and sphenoid," and he appears to lay stress upon the mode of dealing with the

agreed with Mr. Davis that it was rare, and that it was not to operate upon the sphenoidal sinus on the supposition that it might cause retrobulbar neuritis although clinically sinustitis, not opththalmitis inflammation. Surgeons ought to be healthy. The association was a rare one.

Mr. A. J. WRIGHT (Bristol) agreed with the opinion expressed by Mr. Davis. When the sinuses were the cause, this could be diagnosed by rhinologists. Unexplained cases were common, and they would all improve occasionally, with or without treatment.

Mr. T. RITCHIE ROBERT (Hull) said that some cases of sinustitis were very difficult to diagnose. He quoted a case, diagnosed as cavernous sinus thrombosis and subjected to drainage relieved the pain, and in which the Wassermann reaction was positive.

Mr. SOMERVILLE HASTINGS (London) found that the association of retrobulbar neuritis and sinus disease was commoner than some of the previous speakers had said. He agreed with Mr. Ritchie Robert that opening the sphenoid sometimes led to immediate improvement although no disease was found.

Sir J. DUNDAS-GRANT (London) discussed the anatomy of the associated parts, and quoted a case in which sphenoidal drainage relieved the pain, and in which the Wassermann reaction was positive.

infected with the human tubercle bacillus from tuberculous mothers. The earliest age at which he had been able to diagnose the disease was fourteen days. He gave an injection of old tuberculin. If the child was infected there was a local and focal reaction. In abdominal tuberculosis an attack of colic with the passage of green motions was observed. Without this test it was very difficult to say whether tuberculosis was present or not. There might be no clinical evidence of the disease. He had followed his cases for years; one child, aged 12, was now alive and well. He had had one death in his series, and that was in an advanced case. He thought that many cases were not recognized. Treatment by tuberculin injections had been very successful. The prognosis was bad when the disease was diagnosed by ordinary clinical means, but good when diagnosed by the test.

Dr. G. BRITON SWEET (Auckland, New Zealand) said that the prognosis of infants suffering from abdominal tuberculosis was greatly improved by the use of tuberculin, especially when of a bovine strain. In a small series of cases of abdominal tuberculosis in infants under the age of one year 5 made a complete recovery after the use of T.R. bovine.

#### THE TREATMENT OF TUBERCULOUS CERVICAL ADENITIS BY RADIUM.

BY  
ECHLIN S. MOLYNEUX, M.R.C.S.,  
Honorary Surgeon, Warneford Hospital, Leamington.

It is not my purpose to go into the pathology of tuberculous adenitis, as this was dealt with fully last year in a very exhaustive paper by Mr. John Fraser. I think it will be generally admitted that the various treatments of this complaint, whether surgical or conservative, as carried out all over the country, have in the past not been very satisfactory.

I am quite ready to admit that an early excision will often cure a patient, but even then he has to undergo the unpleasant and painful ordeal of an operation, and a scar of greater or lesser size is left to disfigure his neck. This is especially undesirable in the case of girls, however satisfactory an artistic and neat scar is to the surgeon. Another objection to operation is that often a skilful dissection has been made to remove the affected glands on one side of the neck, and much to the surgeon's disappointment the debilitating effect of the operation has apparently caused a fresh outbreak of the disease on the opposite side which had previously appeared healthy. Conservative measures are usually very lengthy, entailing long visits to the sea or Switzerland, and too often failure at the end of it. It is for this reason that I put in a plea for a method which I have been practising for over ten years with excellent results.

##### *Treatment by Radium.*

During the whole of this time I cannot recollect a case that has not been benefited, and I think I am right in saying that only one patient who conscientiously had the treatment carried out has not been apparently cured. This means that one can almost promise to cure a patient whether the disease is early or advanced. The treatment is painless and perfectly safe, provided that scrupulous attention is paid to the technique; I say this because recently a few cases have come under my notice where harm instead of good has been done by wrong doses of radium. Caseating masses of glands, suppuration and secondary infection, and old sinuses are no bar to radium treatment. Unless suppuration has already occurred no scar is left. The skin is sometimes a little red for a few weeks from the effect of the secondary beta rays thrown off from the screen covering the radium—more will be said about this later; the redness always disappears. The one disadvantage of this form of treatment is the cost of the radium and the ease with which applicators are damaged and sometimes lost and thrown away with the dressing.

The period during which I have been doing this work has been sufficiently long to judge whether the cures are permanent. It is excessively rare to find any recurrence

of the trouble once it has been apparently cured. The very few recurrences I have seen have responded to a second treatment. In cases of doubtful diagnosis it has been my practice to remove a small piece of affected gland and have sections cut, and if necessary have a Wassermann reaction taken as well.

##### *Technique.*

It is unnecessary to go to the length of describing all the initial experiments and the concentrations of radium used. The following is the technique which I now employ. The applicators I use are flat ones; the most convenient size is a square one, one inch square containing the equivalent of 15 mg. of radium bromide. This is the concentration that must be used; I actually use the radium sulphate as it is insoluble in water, but in measuring it one speaks in this country in terms of radium bromide. The radium is spread out on the applicator, which is a plaque of silver 3 mm. thick. It must be mixed with some basic to cause the radium to adhere to the applicator evenly and to prevent loss. I used to employ a special form of varnish with this object, but varnish perishes and is easily cracked if the applicator should be dropped, with consequent loss of part of the radium. Recently I have used applicators in which the radium is incorporated with a form of cement instead of varnish, and these are less liable to damage. The applicator has over it a screen of 1 mm. of silver, then a couple of layers of lint, and finally a couple of layers of thin gutta-percha tissue tied over the whole to prevent any soiling of the screen. The gamma rays of radium are used for this work; the screen of silver absorbs the alpha and beta rays, which if used for a sufficiently long application would cause a burn. A silver screen 1 mm. thick will absorb all the alpha rays and 99.9 per cent.—that is, practically all—of the beta rays. When gamma rays emerge from a metal surface such as a silver screen, secondary beta rays are set up whose action on the tissues is the same as that of the primary beta rays, and it is necessary to provide for their absorption. The layers of lint and gutta-percha tissue absorb these irritating secondary beta rays. The applicator thus protected is strapped to the patient's neck, or wherever the tuberculous glands are. Four hours is, on the average, the correct time for the application. I usually employ two or more applicators in order to cover the diseased area at one sitting.

##### *Dosage.*

The frequency of the dose should be twice a week to begin with, and once a week when the glands are markedly subsiding; this is an average frequency, but the effect must be watched and each case judged on its merits. Patients vary greatly in their reactions to radium, some getting well with very few applications, and others requiring many. I have known a mild case recover after two applications, but this is quite unusual. Broadly speaking, patients with early tuberculous glands recover soonest; then those in whom the glands have suppurred; the fibrous type of tuberculous glands and those with large caseating masses that have not become liquefied take the longest time; they often take months to cure.

Treatment is continued until all signs of the disease have disappeared, or, at the most, some fibrous nodules are all that remain. These were for years a source of perplexity to me; an American colleague, however, excised a considerable number and had sections cut. He stated that they consisted of scar tissue and presented no signs of any active disease. If a patient when first seen has a cold abscess I always aspirate the pus under local anaesthesia in order to relieve tension of the skin before starting treatment. If, as occasionally happens, the caseating material is too thick to aspirate, I make a tiny incision with a tenotomy knife and squeeze the pus out. Two or three aspirations are usually sufficient.

##### *Conclusions.*

The following appears to me to be a possible theory as to how the radium acts. In treating cancer one gives a dose which causes a maximum amount of destruction; this, then, is a destructive dose of radium. In treating a tuberculous gland the dose of radium employed is of exactly the

turbinated bodies rather than on the site of access to the interior of the antrum, which is, in my opinion, the essential feature of the operation. A few more details with regard to this latter point might have been given with advantage, and I venture to supplement Canfield's description by adding them in the form suggested by my experience.

For half an hour before the operation the vestibule and anterior part of the nasal fossa should be plugged with a 10 per cent. solution of cocaine hydrochloride in the full strength (1 per 1,000) solution of adrenaline, on ribbon gauze, or preferably non-absorbent cotton-wool.

At the operation (under a general anaesthetic) the head should be slightly raised as for the subnasal resection of the nasal septum, and the posterior nostril should be plugged. A nasal speculum—by preference Killian's shortest type—is introduced and turned outwards, so as to expose the outer wall of the vestibule of the nose. The cocaine plug having been removed, an intranasal incision is made with a short-bladed scalpel down the fold described above as corresponding to the margin of the piriform fossa. This should go down to the bone and hug its outer surface. Skilful removal of an elliptical piece of tissue by making

two incisions meeting above and below. A peristomum elevator is then introduced, and slid quickly up and down so as to detach the peristomum to the depth of about half an inch, carefully avoiding the infraorbital nerve. Then with the greatest decision a flat strip of gauze (two or three ply) is pushed between the bone and peristomum, the outer end being turned outwards over the cheek. The bleeding being thus checked, the nasal mucoperistomum is raised by means of a narrow elevator introduced through the same incision but on the nasal side of the body edge. The elevator is then pushed inwards under the inferior turbinated body for about three-quarters of an inch (avoiding the orifice of the nasal duct).

To make a flap an incision is now made from the top of the original one down the whole of the anterior margin of the inferior turbinated body and for a short distance along its inferior margin the mucoperistomum is detached, and a portion of the turbinated bone resected by means of flat punch forceps. By a transverse incision across the roof and walls of the inferior meatus this mucoperistomal flap may be formed for insertion into the floor of the antrum when the opening is made.

The insertion of such a flap is not, however, of very great importance, and it will be found sufficient to remove the anterior third of the inferior turbinated body. A strip of gauze is now introduced so as to check the bleeding, which, if the preliminary adenoidalization has been well carried out, is seldom great, though otherwise considerable.

FIG. 2.—Author's hooked osteotome.

The opening in the bone is now to be made. A Killian's speculum, usually the middle-sized one, is introduced through the original vertical incision with one blade on the facial surface of the bony ridge and the other on the nasal one. The ridge being freely exposed, a flat chisel is introduced at the lower part with its cutting edge horizontal, pointing backwards and outwards. An assistant hammers on it with a leaden-headed mallet so as to cut into the bone for about the third of an inch. The chisel is then extracted and replaced at the upper part, level with the line of attachment of the inferior turbinal, and is driven into the bone to unite the facial extremities of the two chisel cuts by a vertical one, which should penetrate the antrum, but as a rule the projecting wedge of bone can be gripped by means of bone forceps and broken off. With the forceps the opening can be enlarged both in the facial and the nasal direction, and the pus, polypoid swellings, and debris of bone removed by means of gauze swabs and cures. The antrum can now be swabbed out with a 10-volume hydrogen peroxide, then with a 3 per cent.

solution of zinc chloride, and a vaselined plug of gauze, preferably encased in a thin rubber finger-coat, introduced. The margins of the opening (Fig. 4) may be trimmed with the bone forceps, especially the lowest part of the nasal side, which should be cut down as near to the floor of the nose as possible. If a mucoperistomal flap has been made,

the plug should be removed and the flap pushed into the floor of the antrum, the plug being renewed. In twenty-four hours this plug is removed, and as a rule it need not be replaced.

The following are notes of a consecutive series of cases in which I have operated by this method:

**CASE I.** Margaret H., aged 18, applied for treatment at Brompton Hospital on account of increasing debility and depression; she was found to have discharged from the left nasal cavity which had existed for three years; she had weekly washings out of the left nostril for a couple of months without cessation of the discharge. Almost immediately after the carrying out of Canfield's operation the discharge ceased completely, there was no fever, and she felt well.

**CASE II.** Harry W., aged about 40, had suffered from frontal headaches for two and a half years and nasal discharge on both sides. On the right side pus was present between the septum and the anterior lip of the hiatus, and on the left side between the septum and the middle turbinal. The opening into the frontal sinus from the nose on the right side was obstructed, but on the left no pus was found in the antrum, though some could be washed out of the frontal sinus. The head was relieved by the washing out of the right antrum and of the frontal sinus; at a later period the Canfield operation was carried out. When seen ten days later he reported that he had complete freedom from pain and heaviness in the head, and that his nose was quite clear.

**CASE III.** Colonel — complained of field discharge on the left side of the nose of over two years' duration; pus was found in the right antrum, and two days later the antrum was opened by Canfield's method. Within a few days after the operation the suppuration had stopped.

**CASE IV.** Henderson P., aged 34, had been rejected from the army on account of signs at the right apex but with absence of bacilli in the sputum. He was sent to Brompton Hospital for Consumption, on account of pain in the chest, cough, and expectoration. He was referred to the throat department, where the right maxillary antrum was washed out, after which the pain in the chest disappeared; he was conscious of nasal obstruction and an offensive smell in his nose; there was a detection of the septum and hypertrophy of the right middle turbinal. The washing out was always evacuated. The radical operation by Canfield's method was carried out early in 1922; the suppuration then disappeared and his chest was soon so clear that it was considered unnecessary for him to attend further. Signs of obstruction in the right nasal cavity were relieved by removal of the middle turbinal.

**CASE V.** Jessie G., aged 23, complaining of cough and pain on the left side of the chest, was found to have nothing definite in the lungs nor any bacilli in the sputum; she had pain in the left frontal region and discharge of which she was conscious. The left antrum was opaque on transillumination, and when washed out was found to be full of foetid pus. In spite of repeated washing out the discharge continued, and the Canfield operation was carried out. In a week's time she was free from headache and a slight coming from the frontal sinus.

## SIR BENJAMIN SIMPSON, K.C.I.E.,

Surgeon-General, I.M.S. (ret.).

SIR BENJAMIN SIMPSON, K.C.I.E., Bengal Medical Service (retired), died in London on June 27th, at the great age of 92. Since the death of Deputy Surgeon-General Parke, on April 10th, 1920, he had been the senior officer on the retired list of the I.M.S. That somewhat doubtful honour now falls to the lot of Deputy Surgeon-General Clarence Cooper, of the Madras Service, who, though just one month junior to Simpson, was actually eight months older.

Benjamin Simpson was born at Clontarf, Dublin, on March 31st, 1831; he was the son of Robert Simpson, solicitor, and was educated at Trinity College, Dublin, where he graduated M.A.; he took the M.R.C.S. in 1852, and the M.D.St. Andrews in 1853. He joined the I.M.S. as Assistant Surgeon on October 20th, 1853, nearly seventy years ago, reached the administrative grade on March 21st, 1882, became Surgeon-General and head of the service on March 20th, 1885, and retired on March 29th, 1890. Though in India at the time of the Mutiny, he did not see service in that campaign. In 1860 he entered civil employ in Bengal, and in 1863 was posted to the medical charge of the mission sent to Bhutan in that year, subsequently serving in the Bhutan campaign of 1865-66, for which he received the frontier medal with a clasp. In 1867-68 he was on special duty on the North-East Frontier of India, and in the latter year was appointed civil surgeon of Darjiling. In 1871 he was transferred to Patna, and in the same year served on the Cinchona Commission. In 1878 he was appointed to accompany the late Maharaja of Kuch Bihar, father of the present ruler, as his guardian, on the first of his many visits to India. In 1881 he was promoted to act in the administrative grade as Deputy Surgeon-General of the Army in Southern Afghanistan, and in the same year was posted as Principal Medical Officer of the Quetta Division. On March 21st, 1882, he was confirmed in the administrative rank, and appointed Deputy Surgeon-General and Sanitary Commissioner of the Central Provinces; subsequently he acted for some time as Surgeon-General of the Punjab and of Bengal successively. On March 20th, 1885, he succeeded the late Dr. J. M. Cunningham as Surgeon-General and Sanitary Commissioner with the Government of India, the title then held by the head of the Indian Medical Service.

On December 20th, 1885, he was granted a good service pension, and on February 15th, 1887, he was created K.C.I.E., being one of the first batch of knights appointed to the Order of the Indian Empire. In 1859 he married Jane, daughter of Brigadier-General Hugh Sibbald, C.B., by whom he had two sons and one daughter, the latter the wife of Brigadier-General Sir A. G. Balfour.

His two chief pursuits in India were big game shooting and photography, and in both he was very successful, attaining considerable skill in the latter when it was a much more difficult art than it is nowadays. When he was Surgeon-General he had rather the reputation of being more intent on his amusements than on his work. The writer of this note, however, was told by a distinguished officer of the Indian Medical Service, who served as secretary to several Surgeons-General, and later himself became Surgeon-General, that Simpson did more work than any other chief under whom he had served. He was a man of the old Anglo-Indian school, who rose very early and got through a great deal of work before breakfast; he had the faculty of knowing just what work he could safely leave to his assistants and subordinates, and he did not himself do work which it was their duty to do—consequently he was free from the cares of his office at an hour when most men were still hard at work. As Surgeon-General he was a strong man, and he raked out of the hands of the Provincial Governments into those of the Government of India—that is, practically into his own hands—a good deal of patronage. Two instances were that in his tenure of office the Government of India took over from Provincial Governments the right of nominating individual officers for civil employ, and the power of appointment to the professorships in the various medical colleges in India. When the question whether medical officers in civil employ should be eligible for military promotion was considered, the Government decided that they

should, giving as two instances of conspicuous success on the part of officers promoted from civil posts to act as military administrative medical officers Sir Benjamin Simpson and the late Deputy Surgeon-General Sir James Thornton, both of whom were civil surgeons in Bengal before their promotion.

## HUGH CLAYTON FOX, F.R.C.S.I.,

London.

MANY will learn with sorrow and surprise of the death, from angina pectoris, of Mr. Clayton Fox, on June 13th, after scarcely more than one day's illness. He presented the appearance of perfect health and vigour, and those who saw him a day or two before his death would have prophesied for him a prolonged life of activity.

He was born in 1864 at Coddensham in Suffolk, and was educated at Needham Market Grammar School. He studied medicine at the Middlesex and Charing Cross Hospitals and ultimately in Dublin, taking the M.R.S.C.Eng. in 1888, and the F.R.C.S.I. in 1901. After an experience of general practice he studied oto-laryngology at the Central London Throat and Ear Hospital and joined the staff of the Metropolitan Ear, Nose and Throat Hospital. He devoted much time to the work of the throat departments of the Brompton Hospital and the West End Hospital for Nervous Diseases. During the war he acted as assistant and deputy (for Sir James Dundas-Grant) at the King George Hospital, as well as at the Endsleigh and Vincent Square Hospitals for Officers.

The Ministry of Pensions afforded him great scope at the aural clinics at Queen Mary's Hospital, Ducane Road Military Hospital, and for the last few years three aural clinics a week at Hammersmith Broadway. Moreover, he was constantly employed on aural boards. Just before his death he had been appointed aurist and laryngologist to the Marylebone General Dispensary.

He made a masterly translation from the French of Laurens's *Oto-Rhino-Laryngology*, which has been in such demand as to call for two new editions in a comparatively short time. His abstracts from French special journals which appeared in the *Journal of Laryngology* were always accurate and practical. Though of a somewhat reserved disposition he acquired a large number of friends, who became more and more attached to him as they learnt to realize the largeness of his heart.

## Universities and Colleges.

## UNIVERSITY OF OXFORD.

At a congregation held on June 28th the degree of Bachelor of Medicine was conferred on E. F. Chapman.

The following candidates have been approved at the examinations indicated:

FINAL M.B.—(*Materia Medica and Pharmacology*): G. R. P. Aldred-Brown, E. N. Allott, L. J. Barford, L. W. H. Bertie, R. B. Bourdillon, V. H. Brink, C. S. Broadbent, T. A. J. M. Dodd, L. O. F. Fysh, S. Harris, T. B. Hodgson, A. Kendrew, R. Lewthwaite, P. Morton, E. L. Newell, W. D. B. Read, T. E. Ryves, B. G. Schofield, R. W. A. Simmons, R. A. Walsh, A. Q. Wells, Evelyn C. Whitehall-Cooke, D. O. Williams, Rosa S. Wordsworth. (*Pathology*): M. McC. Baird, R. E. D. Carrigill, C. W. Carter, T. A. J. M. Dodd, C. L. Elgood, K. J. Franklin, D. R. Gawler, C. A. H. Green, H. E. Harding, J. R. B. Horn, J. A. Macfadyen, V. P. Robinson, J. P. Shaw, I. M. Sidley, H. N. Stokoe, J. G. S. Thomas, B. E. Tompison, G. P. Wright. (*Mathilde E. Bugnion, Janet M. Vaughan. Forensic Medicine and Public Health*): O. D. Ballinger, D. T. Barnes, E. F. Chapman, A. M. Cooke, R. S. Creed, R. van B. Emmmons, J. A. Macfadyen, G. F. L. Mitcheson, E. B. Strauss, T. S. Townsend, H. F. Turney, Cicely D. Williams. (*Medicine, Surgery, Midwifery*): J. W. Alden, P. W. Boobyer, T. A. Brown, A. D. Dyson, R. van B. Emmmons, R. V. Facey, H. O. Hill, J. P. Shaw, A. L. B. Stevens, E. H. Watkins, A. Q. Wells, C. R. Young, W. A. Young, Sibyl R. Eastwood, Cicely D. Williams.

M.Ch.—C. H. Carlton.

## UNIVERSITY OF SHEFFIELD.

The following candidates have been approved at the examinations indicated:

M.D.—R. Platt.

FINAL M.B., Ch.B.—O. H. Billington, R. L. Brown, Alice C. Caiger, Ida Coates, H. Cretnay, A. S. Drummond, C. S. Dunbar, D. Guest (Second Class Honours), W. H. Harding, Mona E. Hatherley, A. B. Nutt, Muriel R. Powell, J. E. Schofield, Annie D. Sykes.

## CASE VI.

Matt. R., aged 32, complained of fetid purulent discharge from the nose confined to the left side, of four years' duration, accompanied by left frontal headache. Transillumination showed opacity of the left antrum, and Lichtwitz's puncture gave vent to a quantity of fetid pus. The middle turbinal was enlarged, and the anterior part of it removed so as to free the infundibulum and the orifice of the antrum. This was followed by relief to the headache, but repeated punctures showed no diminution of the amount of pus. Canfield's operation was performed, and in a few days the purulent discharge had completely disappeared. A small mass of granulations developed on the anterior margin of the opening, which interfered with the introduction of a cannula, but after this was removed there was no further difficulty.

## CASE VII.

Mr. F. L. B., aged about 50, was the subject of a paper read by me at the Newcastle meeting of the Association, as a "case of ganglion neurosis," suggesting malignant disease: operation antrum was translucent on transillumination, and no pus was washed out by means of Lichtwitz's trocar and cannula. Canfield's cavity was found free from pus or new growth; there was, however, a vertical bony partition shutting off the posterior part of the cavity; this was broken through by means of a strong spoon, giving vent to a quantity of soft granulation-like tissue, bathed in pus; convalescence was retarded by a streptococcal infection which yielded to injections of antistreptococcal serum, and recovery was complete. The patient found no difficulty in washing out the antrum through the convenient opening afforded by this operation. Further details and skiagrams will be found in the *Journal of Laryngology and Otology* for February, 1922.

## CASE VIII.

Nellie D., aged 25, who had suffered for a number of years from pulmonary trouble, with cough and profuse expectoration, was referred to me in May, 1921, on account of a purulent discharge from the left nasal cavity. I did not see her again till September, 1922, when an alveolar puncture was made and pus washed out. In February of the present year there was still fetid pus in the left antrum. Canfield's operation was at once performed. Some discharge still continued to flow, but this was found to come from the frontal sinus, and it disappeared after removal of the frontal part of the middle turbinal and the washing out of the frontal sinus with argyrol on three occasions. An accompanying headache on the left side disappeared, and the physician reported such great improvement in the chest conditions after the treatment of the antrum that further attendance on that account was unnecessary. The left antrum is now quite dry, and on transillumination quite translucent.

In this case, for the first time, I have made use of the notched osteotome, having experienced the tendency of the straight-edged chisel to slide off the sharp ridge of bone.

## CASE IX.

Mrs. W., aged 55, was operated on through the nose a number of years ago, before the adoption of the Canfield method, on account of chronic suppurative inflammation in the left maxillary antrum. There was still a discharge of pus, and it was proposed to perform Canfield's operation on the antrum. In May, 1922, she developed suppurative inflammation in the right antrum with extreme pain and headache. In July I performed Canfield's operation; the pain disappeared at once, and the suppurative ceased in a few days; it has not returned, and the opening into the antrum is still patent.

## CASE X.

Mr. J. W., aged 38, was operated on in 1912 by the old intranasal method for chronic empyema of both antra. The right one settled down completely, but the left one continued to discharge. I performed Canfield's operation, and at once the headache and mental depression from which the patient suffered disappeared completely. In this case the antrum contained a number of polypi. The discharge disappeared almost at once.

In this case the operation was facilitated by the use of the notched osteotome.

The enormous improvement in general health which follows this operation has certainly done so in other forms of radical procedure, but in none—in my own experience—has the improvement been so rapid.

I may mention that exception has been taken to this operation on account of the amount of bleeding, which was extremely troublesome in my earlier cases. Since the adoption of the methodical cocaine-adrenaline preparation insisted on by my friend Mr. Clayton Fox, and the "decided" insertion of the gauze strip on the facial surface of the bone, this has become quite insignificant.

Though this may be considered a rhinologist's operation, I venture to think that the details I have here given will place it within the scope of others. Its efficacy may well be tested in cases in which the more usual methods have failed to give complete satisfaction, and I have every confidence as to the result.

## BUTYN AS A LOCAL ANAESTHETIC IN NOSE AND THROAT PRACTICE.

BY

WILLIAM HILL, M.D., B.Sc.,

Consulting Surgeon for Diseases of the Throat, Nose, and Ear to St. Mary's Hospital, and Endoscopic Surgeon to the Metropolitan Ear and Throat Hospital.

ALTHOUGH the alkaloid cocaine was isolated from the leaves of the coca plant so far back as 1860, it is only during the last forty years that it has been generally used as a local anaesthetic in the form of its most soluble salt, the hydrochloride. In the early days of its employment serious toxic and even fatal effects were occasionally reported, and this soon led to efforts to discover any equally efficient local anaesthetic substance considerably less toxic than cocaine and free from those exhilarating properties which have resulted in its becoming a drug of addiction; thus during the final decade of the last century the synthetic alkaloidal substances eucaine, stovaine, and orthoform were brought out, to be followed early in the present century by anaesthetics and novocain, to mention only some of the more widely employed local anaesthetics.

These agents, however, whether on account of their salts being sparingly soluble in water or of their transitory effects, failed to displace cocaine entirely. The hydrochlorides of eucaine, novocain, and stovaine proved reliable anaesthetics for infiltration anaesthesia by injection in weak solution, and comparatively free from toxic effects, and they have supplanted cocaine in this method of local anaesthesia. Again, the very sparingly soluble powders, orthoform and anaesthesine—both benzoates—have proved useful local anaesthetics for insufflating on to ulcerated surfaces in cancer and tuberculosis of the throat.

For the production of local anaesthesia by surface application to mucous membranes as a preliminary to surgical procedures none of the above substances, however, proved really efficient, and cocaine hydrochloride remained not only pre-eminent but the only possible local surface anaesthetic for surgical requirements in the nose, throat, and elsewhere.

With the full recognition that caution must be used in the employment of much cocaine for surface anaesthesia and that toxic effects occur in certain susceptible individuals, they are occurrences of extreme rarity and fatal results have apparently been conspicuous by their absence in recent years. Cocaine having been superseded in infiltration anaesthesia by substances far less toxic and equally efficient, it may be confidently expected that it will one day be supplanted as a mucous surface anaesthetic by the discovery of a substance which is equally efficient but far less generally toxic, having no such special toxic effects to which a small number of individuals are keenly susceptible and possessing no properties likely to lead to its becoming a drug of addiction.

As the result of prolonged experiments, the expert staff of the Abbott Laboratories of Chicago, working in collaboration with Professors Adams and Kamm of the University of Illinois, have produced a synthetic substance—*butyn*—which is readily soluble, and which, it is claimed, fulfils most of the requirements of a safe and efficient cocaine substitute. *Butyn* is not a cocaine derivative, and there are therefore no restrictions as to its purchase, but, like the other local anaesthetics mentioned above, it is chemically related to cocaine, as will be seen from the following table.

## Ethyl series:

- (1) Novocain = Para-amino-benzoyl-di-ethyl-amino-ethanol hydrochloride.
- (2) Anaesthesine = Para-amino-benzoic-ethyl-ester.

## Methyl series:

- (3) Cocaine = Methyl-benzoyl-ecgonine.
- (4) Eucaine = Trimethyl-benzoxypiperidin hydrochloride.
- (5) Orthoform = Methyl-amino-oxy-benzoate.

## Butyl series:

- (6) *Butyn* = Para-amino-benzoyl-gamma-di-n-butyl-amino propanol sulphate.

A committee appointed by the American Medical Association reported early in 1922 very favourably on *butyn*, as the result of extensive investigations of its clinical employment, more especially in eye work. Beaumont of Bath con-

# British Medical Journal.

## THE INSURANCE CRISIS.

THE executive bodies of Approved Societies have sent to the Minister of Health a long "statement of the Societies' case against the proposal to appropriate towards the remuneration of panel doctors for the present type of medical service sums contributed by the insured population and their employers for other benefits." This quotation from the preamble to the statement itself embodies an untruth, and the statement contains several assertions which can be similarly characterized, as well as a larger number of others which seem to be deliberate suggestions of what is false. It is unnecessary to traverse them all. The Societies' letter is too long and involved to be read by those who are not directly interested; those who wish to believe what it contains will no doubt do so in any circumstances; those who know the facts will detect the misstatements with relative ease. In general the statement shows not only a complete misapprehension of the work of the medical profession, and of the contentions of insurance practitioners in the present controversy, but also a failure to appreciate the very elements of what an insurance scheme implies—a matter the writers might be expected to have studied before setting out to instruct the Minister and the public. To take only two examples: the Societies contend that because drugs were not prescribed on the occasion of every attendance on a patient all the other attendances were not "essential" and therefore ought not to be "taken into account"; and that it is improper, if not illegal or immoral, for doctors to receive any insurance credits for insured persons who are not ill or who do not consult them when they are ill. It is strange that contentions so absurd should be put forward in a document evidently intended to be taken seriously.

The letter of the Societies makes abundantly clear how necessary it was to obtain from the Minister the declaration which is placed in the forefront of his new offer (printed in last week's SUPPLEMENT, p. 209), and how great will be the gain to the profession if it is put effectively into practice, as it must be assumed will happen if the profession accepts one or other of the Minister's alternatives. The Societies explicitly claim that additional benefits take priority of the full payment for medical attendance and treatment determined on its merits if this should be more than a certain sum. It may be pointed out that the Act of 1911 does allow additional benefits in certain circumstances to be substituted for sickness and disablement benefit, but in no circumstances does it allow medical benefit to be touched. The Societies describe the contention (accepted by the Minister) that medical attendance and treatment should first be provided for as an "astounding proposition." The framers of the Act evidently regarded it as axiomatic, and no doubt the public generally, as well as the insured persons, will agree. Societies would soon become aware of it if insured persons were allowed to claim sickness benefit apart from medical treatment.

Again, the Societies dispute the allegation that they desire to dominate the insurance practitioners or the insurance service. They merely "take an interest in the fees paid to doctors"—an interest so keen that they dispute the right of the Minister to negotiate with the profession for its services to the community without their intervention, or his right to offer one penny beyond what they are pleased to approve. If the medical profession did not combat this to the utmost, "interest" and "domination" would have to be accepted as synonymous terms. Let it be admitted at once that the Societies have an absolute right to be heard as to the "source whence the money is to be derived." They have a vital concern in the National Health Insurance Fund. This the profession has never disputed, but it carries with it no right to be a party to determining, on its merits, what insurance practitioners ought to be paid for their services. The Societies' letter concludes by expressing "their determination to resist to the utmost the unjust demand of the British Medical Association that the insured persons' funds should be raided." Neither the Association nor anyone else authorized by the profession has made any such demand. Nor has the Association ever contended, as the letter alleges, "that there are other National Health Insurance Funds from which money can be found." This, like other such statements, is a myth. The contention of the Insurance Acts Committee is that, on the merits of the case, there is no justification for reducing the present capitation fee; and its belief is that the present state of the Fund in the aggregate would allow this fee to be met from that source without danger to other interests. The Committee has been led to this belief by an investigation by its own experts; it has been confirmed therein by the fact that two of the signatories to the Societies' letter have themselves signed the following statement: "We have satisfied ourselves that the National Health Insurance Fund in the aggregate contains sufficient money to meet the cost without lowering or endangering the revision of the other benefits (whether normal or additional) to which insured persons are entitled," and by the further fact that an identical conclusion has been accepted, after investigation, by the Trades Union Congress General Council and the National Executive of the Labour Party.

These matters of insurance finance, of Approved Society administration, and of the granting of additional benefits will, amongst others, be the subject of inquiry by the Royal Commission which the Minister of Health has promised. We understand that attention was immediately drawn to the Prime Minister's statement at Swansea on October 30th, "that the Royal Commission would examine especially the question of medical benefit," and that no such limitation of the inquiry is in fact contemplated. It will, on the contrary, be the full inquiry that the Insurance Acts Committee has asked for. The Minister of Health has informed the Committee that a Royal Commission will be set up to investigate and report on the whole system established under the National Health Insurance Acts, including medical benefit and the remuneration of practitioners, and has promised that the terms of reference to this Commission will be agreed with the profession. In his speech at Manchester on November 2nd the Prime Minister also indicated that the Government also proposed "to examine and co-ordinate and improve the existing schemes of insurance, and adjust those evils that

tributed a paper to the *BRITISH MEDICAL JOURNAL* in January of this year confirming from his own eye practice the favourable impressions received from America. Bulson and others in the United States have also used butyn extensively in nose and throat practice, as a surface anaesthetic, with fairly good results.

The claims made for butyn are as follows:

1. It is a powerful local anaesthetic, being about twice as potent as cocaine, so that a 5 per cent. solution of butyn suffices in nasal surgery, for example, where a 10 per cent. solution of cocaine hydrochloride would be necessary.
2. Butyn acts more quickly than cocaine and its effect lasts longer. This may be an advantage in eye work, but, as will be pointed out later, is a decided disadvantage in nasal practice.
3. It is less toxic than cocaine; possibly only half as toxic dose for dose, and as only half the quantity of the drug is necessary its toxicity in practice is still further reduced. The point of real practical importance is that although butyn has been employed many thousands of times in America, more especially by ophthalmologists, no record of any serious toxic complications appear to have been reported up to now.
4. It has no ischaemic effect when applied to mucous surfaces. This may be an advantage in eye work, but, as will be pointed out later, is a decided disadvantage in nasal practice.
5. It can be boiled without impairing its anaesthetic potency, and it does not deteriorate on keeping, as does cocaine.
6. It gives rise to no exhilarating and pleasing effects, and is therefore not likely to excite craving and become a drug of addiction.

I find the *disadvantages* of butyn are as follows:

1. On the appearance of Mr. Beaumont's paper more than six months ago I purchased some butyn, and was at once confronted with one of the drawbacks to the employment of this drug, as the price was 6s. a gram in powder and 6s. 6d. in tablet form; that is to say, the cost is at present five times that of cocaine, and even taking into consideration the fact that a gram of butyn goes as far as two grams of cocaine hydrochloride, butyn is two and a half times as expensive to employ at the present time.
2. Cocaine hydrochloride is a very reliable surface anaesthetic for mucous surfaces, although inflamed surfaces require a longer application and may demand an increased percentage solution; on the other hand, *butyn is not uniformly reliable*. It was not until my seventeenth observation with butyn that I found it quite failed, in spite of renewed applications in that case, to render the mucosa of the septum sufficiently insensitive to tolerate the galvano-cautery. Beaumont made no mention of this occasional failure of butyn to anaesthetize. There is a French aphorism which advises that in the case of a new remedy we should hurry up and employ it whilst it continues to act. On referring to Bulson's report I find that others have noticed that certain individuals, not a large number probably, have failed to respond to butyn. I have had to resort to cocaine in addition on at least four occasions during the last six months, which represents about a 5 per cent. failure in my nasal series. This is to my mind a serious drawback, and in marked contrast to the reliability of cocaine hydrochloride.
3. The most disadvantageous characteristic of butyn as far as the rhinologist is concerned is that it not merely fails to produce ischaemia of the mucosal vessels and general shrinking, but that it has a tendency to bring about hyperaemia and tumefaction. In many rhinal procedures, whether for examining or other purposes, reduction of tumefaction of the mucosa is as essential as anaesthetization. It is recommended that an ischaemic effect can readily be obtained by adding adrenaline, or some similar suprarenal product to the butyn solution. No rhinologist, however, needs to be reminded that adrenaline has in many individuals, and especially in inflammatory conditions in the nose, an extremely irritating action, sometimes causing an intense coryza most distressing to the patient and lasting two or three days. Since I have been testing the effects of butyn reinforced by adrenaline solution I have produced such a distressing coryza on several occasions. For operation under local anaesthesia on the sinuses and on the septum and for the removal of polypi this complication cannot be provided against by using cocaine hydrochloride instead of butyn, because for haemostatic purposes we are accustomed to reinforce the ischaemic effect of cocaine by the addition of adrenaline, and as large surfaces have to be anaesthetized in the above-named procedures we have here a useful field for the employment of butyn instead of cocaine hydrochloride so as to minimize the chance of toxic effects occasionally incidental to exhibiting a considerable quantity of 10 per cent. solution of cocaine hydrochloride. It has been already pointed out, however, that marked toxic effects following the use of fairly large amounts of cocaine hydrochloride solution up to 10 per cent. potency are of extreme rarity, and that such a complication depends far more on intolerance to cocaine in exceptional individuals than on the actual amount of cocaine applied to mucous surfaces and liable to be absorbed. In vasomotor rhinitis and in the rhinitis of influenza and similar acute and subacute conditions where the ostia of the sinuses are liable to become blocked and where application of weak solutions of cocaine hydrochloride often affords an immense amount of relief by anaesthesia and ischaemia, adrenal preparations are contraindicated on account of the irritation and hyperaesthesia being thereby intensified, so that for these conditions butyn finds no useful field of employment.

In my rhinal practice the application of butyn solutions has recently been almost entirely restricted to galvano-

cautery applications to the septum and to the inferior turbinates, but even here, except in individuals who are proved to be especially susceptible to cocaine, it is doubtful if anything worth mentioning is gained by using this expensive agent.

What has been said in reference to the shortcomings and restricted field of usefulness of butyn in the nose applies in a somewhat lesser degree to the pharynx and larynx, which are not so susceptible to irritation by adrenaline. I have on two occasions failed to get sufficiently good anaesthesia with butyn to carry out with comfort to the patient galvano-cautery to the base of the tongue for the relief of paraesthesia. My use of butyn in the throat has not been very extensive owing to my increasing loss of confidence in the drug on account of its occasionally proving unreliable.

In conclusion I must record my opinion that butyn cannot claim to be a reliable and efficient all-round substitute for cocaine in nose and throat practice, but it is a useful alternative in a few conditions, more especially where cocaine is contraindicated.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### HYDROCEPHALUS FOLLOWING SPINA BIFIDA.

A TWIN, aged five weeks, was admitted to the General Infirmary, Leeds, with a large thin-walled meningocele in the lumbar region. Both legs were paralysed, the one quite flaccid, the other showing some resistance to movement. There was a suspicion of condylomata in the anal region, and the facies suggested a syphilitic taint, but the family history was good, and the other twin to all appearance healthy.

At operation it was found that all the lumbar laminae were wanting, and that the cord was lying on the posterior surfaces of the vertebral bodies. The sac was excised. In the belief that spina bifida is a symptom and not simply a congenital defect, I threaded silkworm sutures from the subdural space into the erector spinae muscles, hoping that thereby the cerebro-spinal fluid would drain off into the muscular spaces. The wound was then closed, but remained unhealed for about two weeks, during which time it discharged cerebro-spinal fluid copiously.

Rapid healing now began, and after three days hydrocephalus developed. As the condition was causing great pain, it was decided to drain the lateral ventricle. I made a curved incision over the parietal bone about one inch above the external auditory meatus. A portion of the bone was removed with scissors, and a crucial incision into the dura made. The brain, thus exposed, was unduly moist. A bundle of short silkworm sutures were thrust into the ventricle, and a large amount of cerebro-spinal fluid welled up. The bundle was secured to the cerebral surface of the dura mater, and the skin drawn together with silkworm sutures. The cranial bones at first moved curiously on each other, but twelve hours later the skull had consolidated. The operation apparently gave relief from the pain, and there was no return of the hydrocephalus during the three weeks following. The spina bifida wound remained closed. One week after discharge the child died. No particulars were obtainable.

The rapid development of hydrocephalus following the healing of the spina bifida wound is a strong argument in favour of the theory advanced by Mr. John Frazer and others, that spina bifida should not be regarded as a purely local defect, but as the sign—in the cord—of increased pressure of the cerebro-spinal fluid. The cause of this increased pressure is probably some interference with its outflow, possibly by adhesions.

My thanks are due to Mr. L. R. Braithwaite for permission to operate on this case, and to publish this account.

A. P. BIRWISTLE, M.B., Ch.B.,  
Late Resident Surgical Officer,  
Leeds General Infirmary

affect the life and health of the people, such as old age and ill-health and unemployment." There is therefore great danger of confusion, and it is difficult to see how all the subjects he enumerated can be combined without overloading even a Royal Commission and postponing any report to an indefinitely remote future. One thing is at any rate imperative. In view of a possible early general election the Royal Commission with the reference indicated by the Minister of Health, sufficiently wide yet clearly defined, must be set up at once, or the promise which is part of the Minister's offer will be in serious danger of never being kept. This would be far neither to the Minister nor to the medical profession. At its meeting on November 7th the Insurance Acts Committee resolved to advise the Conference of representatives of Local Medical and Panel Committees on Wednesday next, November 14th, to accept the Minister's offer, and decided by a majority to recommend acceptance of "alternative b"—the proposal to set up an immediate Court of Inquiry to determine the appropriate capitation fee for 1924.

## LETHARGIC ENCEPHALITIS AND HERPES

### FEBRILIS.

The researches carried out in recent years on the nature of the infective agent causing lethargic encephalitis have shown that the filtrable virus obtained from lesions in man, when introduced into susceptible animals, becomes localized in the central nervous system, travelling to it along the nerve trunks, but that the blood and internal organs, with the exception of the liver, do not contain it. Researches on herpes febrilis (or labialis) have shown that the virus contains a filtrable virus, infectious to the rabbit, and in a lesser degree to the guinea-pig and mouse. When the virus is scratched into the cornea a lesion is produced which can be transferred from rabbit to rabbit, but no visible micro-organisms have been found in the discharge from the conjunctiva. Nevertheless the diluted filtered discharge, when inoculated into the brain of a rabbit, produces all the symptoms of lethargic encephalitis and leads invariably to the death of the animal. Consequently it is held that the virus of encephalitis lethargica and that of herpes febrilis are closely related if not identical. There are other infections in man and animals related to herpes febrilis and encephalitis lethargica the causal agents of which are unknown. Thus certain clinical observations appear to indicate that epidemic chicken-pox may originate from a case of herpes febrilis, and certain experiments prove that the cornea of a rabbit may be infected by the contents of the chicken-pox vesicles. Lévaditi thinks that the virus of mumps may be closely related to that of lethargic encephalitis, and certain infections of animals, including foot-and-mouth disease, are believed to belong to the same category. Szynamonowski and Zyberlast-Zand, working at Warsaw, have made a special study of the symptoms and pathological lesions in encephalitis lethargica and encephalitis febrilis. They obtained the material for the former experiments from a patient suffering from herpes and transferred it to the cornea of rabbits, all the experiments yielding the same results. The symptoms and pathological lesions in encephalitis lethargica and encephalitis febrilis are identical. They react differently, since in man their affection plays an important part in the pathological picture. This, and also the involvement of the liver, are arguments against Lévaditi's hypothesis of a special affinity for the cornea of rabbits, all the experiments yielding the same results.

The course of the disease was either positive result. The course of the disease was either acute or chronic, and inoculation of the same material subdurally caused cerebral changes manifested clinically by a series of nervous symptoms, such as unnatural positions of the head, stereotyped circus movements of the body, profuse salivation, stiffness of the jaw, and paresis. Post-mortem examination of the brain revealed pathological changes identical with those due to lethargic encephalitis. In studying material cerebro-spinal fluid and discharge from the nasopharynx of patients suffering from lethargic encephalitis, and emissions of the brains of patients dead of this disease. The infective material was introduced into the eye and under the dura mater of the brain or spinal cord. Fifty-five inoculations gave late healthy rabbits with brain emissions of rabbits infected with lethargic encephalitis, but here met with difficulties, since a secondary infection destroyed a large number of the animals. They found it much more difficult to infect rabbits with material taken from other infected rabbits than with material from human cases. Still, in the positive cases the clinical symptoms of infection by lethargic encephalitis were identical with those of herpetic infection, though the local changes in the eyes were more intense in herpetic infections. The pathological changes are, they say, identical in both infections. In the acute form of the disease there was a well marked infiltration of the pia mater all over the brain; in some places the blood vessels showed perivascular infiltration, and in the brain tissue, principally in the region of the lentiform and caudate nuclei, there were foci of cellular infiltration, consisting of mononuclear elements (large mononuclears and lymphocytes). The mononuclear infiltration was a constant feature, even in the most acute cases that proved fatal in two days. In the chronic cases there was much less small cell infiltration than in the acute, but more proliferation of the connective tissue in the meninges, and polyblasts and plasma cells were found in the nervous tissues. The reason why animals infected with the virus of herpes or lethargic encephalitis so often develop circus movements and disturbances of static position has not received a satisfactory explanation. It may be that in animals the virus has a selective affinity for the vestibular nerve as it has for the oculomotor nuclei in man, or there may be a special arrangement of the blood vessels or some peculiar biochemical properties of these nuclei. In all the animals infected with either virus in hamamatory changes were found in the liver, consisting of a mononuclear infiltration round the small bile ducts; the inflammatory cells often penetrated between the epithelial cells, which were occasionally much proliferated. The liver was congested, and the cells around the blood vessels were often destroyed. These authors believe that both the liver and brain are affected simultaneously.

There are many characters common to the infection of man and animals with these viruses; the infiltration consists of mononuclear cells in both, its degenerative changes in the cerebellum occur in man as well as in the rabbit. The meninges, however, react differently, since in man their affection plays an important part in the pathological picture. This, and also the involvement of the liver, are arguments against Lévaditi's hypothesis of a special affinity for the cornea of rabbits, all the experiments yielding the same results.

## A SPORADIC CASE OF MYOCLONUS MULTIPLEX.

The following notes on a man who was stated to have delusions and hallucinations may be of interest.

J. W., aged 56, was admitted to the Littlemore Mental Hospital on September 20th. On admission he was in a condition of stupor. The temperature, pulse, and respirations were normal and remained so throughout the course of the disease. Marked myosis and the Argyll Robertson pupil were present. The consensual and sympathetic reflexes were absent. The biceps and triceps reflexes were absent. The abdominal reflexes were brisk. The abdominal wall was rigid and hyperaesthetic. The knee-jerks and ankle-jerks were absent. Indefinite Babinski and Oppenheimer signs elicited on the right side; on the left the plantar reflex was normal. Both protopathic and epicritic sensibility were increased in both legs, and more especially in the right foot. Myokymia and myotatic irritability were well marked.

Convulsive attacks of a myoclonic type occurred on the second day. The muscular contractions started in the legs or abdominal wall, and soon became generalized. They were regular, rhythmic, and forcible, and occurred at the rate of thirty to forty a minute. Each seizure lasted from three to four minutes. The left pupil now dilated slightly and reacted sluggishly to light. Signs of a transient meningismus now appeared—slight head retraction and Kernig's sign, the latter being more definite on the right.

A fortnight after admission the stupor was less profound and the patient answered questions with a feeble stammer. The pupils were of normal size and reacted to light and accommodation. The meningismus and myoclonus had passed off. The abdominal reflex was now absent on the right side, and the Babinski and Oppenheimer signs were quite definite. There was slight frontal headache. The white cell count was 8,756 per c.mm. A differential count showed a slight relative increase of the polynuclear type. The cerebro-spinal fluid was clear and under normal pressure. A cell count of the centrifuged deposit showed two mononuclear cells per cubic millimetre.

The Lange colloidal gold reaction was negative, as was the Ross-Jones test for globulin. Twenty-four-hour cultures at 37° C. were made from the centrifuged deposit on blood serum and agar with negative results.

The patient is under treatment by intestinal antiseptics and full doses of hexamine and appears to be gradually improving.

Littlemore, Oxford. J. CAMPBELL RAMSAY, M.B., B.Ch.

FACIAL PARALYSIS FOLLOWING HERPES  
FACIALIS.

I DESIRE to record a case of facial paralysis following herpes similar to the case of herpes zoster with muscular paralysis reported in the BRITISH MEDICAL JOURNAL of June 9th, 1923 (p. 970).

A. L. R., sanitary inspector, Bengali, Hindu, aged 33, went on duty on a long and arduous bicycle journey on March 28th, 1922, when he received a severe wetting. On his return at night to headquarters he had headache with slight fever (100° F.), for which he took 10 grains of quinine and 5 grains of aspirin.

On the following day an attack of herpes facialis developed, affecting the pinna and external meatus of the left ear, together with the skin in the neighbourhood of the mastoid eminence.

On April 3rd, on awaking in the morning, he felt giddy and subsequently noticed that his face was drawn to one side. On medical examination it was found that he was suffering from well marked facial paralysis. He was unable to shut his left eye, to whistle, or to chew food properly. His sense of taste was also defective, as well as his sense of hearing on the affected side. These symptoms were accompanied by vertigo with a tendency to fall to the left, which in the event proved to be so severe and persistent as to incapacitate him from work for over five months. There was also a very considerable degree of sleepiness and mental hebetude, and a sense of general physical weakness.

Slight facial paralysis still persists after more than one year's convalescence, with some impairment of former mental acuity. A feeling of vertigo and pain in the left parietal region is also experienced on exertion, especially after cycling.

The sleepiness and mental dullness noticed in this case are particularly interesting in view of the close relationship stated by French investigator to exist between the virus of herpes and that of encephalitis lethargica.

Asansol, Bengal.

J. W. TOMB, M.D., D.P.H.

## Reports of Societies.

## SPINAL ANALGESIA.

At a meeting of the Section of Anaesthetics of the Royal Society of Medicine held on November 2nd, with the President, Dr. A. L. FLEMING, in the chair, Dr. HENRY FEATHERSTONE communicated a critical report on 100 cases of spinal analgesia with tropacocaine. The paper dealt with the selection of cases, the administration of the drug, the condition of the patient, the local effects of the drug at operation, and the ultimate progress.

Discussing the selection of cases, he said he had never been wholly convinced that spinal analgesia, where its employment was permissible, was as satisfactory as general anaesthesia, owing to mental distress on the part of the patient and lack of his co-operation, the possible failure to insert the needle, especially in the obese and in the deformed, the possible deterioration of the drug, the limitation of the time available for operation, and the added strain on all the theatre workers. The series included cases suffering from prolonged or severe trauma 26, toxæmia or shock from intestinal obstruction, etc., 6, acute shock from trauma 2, lung affections 15, affections of air passages 6, pre-operative exposure to infectious colds 3, obstruction of larynx by enlarged thyroid 2, tuberculosis 5, heart disease 6, venous thrombosis of thigh and pelvis 1, albuminuria 2, diabetes 2, eclampsia 2, senility 3, enfeebled general condition 2, Caesarean section 12, uterine haemorrhage 1, objection to general anaesthesia 7.

In regard to results, one patient with crushed lower limbs died and the other recovered, but this type of anaesthesia was rarely employed for such cases owing to the dangers of a falling blood pressure. Pneumonia developed in 2 cases with respiratory affections and both recovered, but these served to show the importance of blood loss and abdominal shock in determining the onset of pneumonia, for both cases had lost much blood. In 6 cases of grave prognosis owing to prolonged intestinal obstruction, strangulation of bowel, and intra-abdominal sepsis, no harm was done by the injection, but shock was not eliminated, especially in the upper abdominal cases. The 5 tuberculous cases all did well, as also did the 6 cardiac cases. The drug gave an excellent result in the case of thrombosis of the pelvic and thigh veins, as the risk of post-operative movement was minimized thereby. The toxæmic cases, albuminuria, diabetes, etc., showed excellent results, and emphasized the importance of a non-toxic method of treatment. The senile cases also were satisfactory, as were the cases in which a general anaesthetic was refused.

Discussing administration, Dr. Featherstone said he preferred to have the patient on his side for the injection, especially as the sitting posture was often contraindicated in these cases. He used a 5 per cent. solution of tropacocaine in normal saline, and varied the dose with the dimensions of the vertebral canal, the level of the anaesthesia required, and the duration of the operation—for example, a big man to be operated upon for an hour below the umbilicus would require 2.5 c.cm., whereas a boy of 8 years, if given 1.5 c.cm. would have high anaesthesia for one and a half hours. The ethyl chloride spray dulled skin sensation sufficiently for incision, and was preferable to nitrous oxide, which caused rigidity of the erector spinae muscles, with consequent difficulty in finding the intravertebral space. The cerebro-spinal fluid must enter the barrel of the syringe before injection, or some of the drug would be lost in the epidural space; the injection should be made through the second lumbar space. There were three causes of the extension of the analgesic area upwards: (1) the drawing off of a considerable quantity of cerebro-spinal fluid, (2) inclining the body with the head downwards, and (3) rapid injection of the drug. In the present series, with a minimal release of cerebro-spinal fluid, 3.5 per cent. of patients developed headaches, whereas with a greater release 78 per cent. complained of this after-effect. Where combined anaesthesia was employed no headache was complained of. The author also cautioned his hearers against the too free mixing of the drug in the syringe with the cerebro-spinal fluid before injection, as in one case where he had done this vomiting, acetone in the breath and urine, and shock lasting for two days resulted. He suggested that the diffusion and dilution of the drug led to more rapid absorption and hepatic shock. Sudden movement caused a more rapid fall in the blood pressure than did gentle movement, but if the patient were gradually lowered analgesia up to the sixth dorsal vertebra could be obtained without discomfort. In the flat position this would extend only up to the umbilicus. Seven deaths occurred among the series, but none died on the table and only

THE SEMON LECTURE.  
 by Dr. Logan Turner of Edinburgh on November 1st, brought together a large audience, including many otolaryngologists from the metropolis and beyond it. An abstract is published in this issue (p. 885), and the full text will, we understand, appear in the *Journal of Laryngology*. In the evening Sir St Clair Thomson held a reception of the members of the two Sections of Otolaryngology and Laryngology of the Royal Society of Medicine, and, to meet them, he had extended invitations to the President of the Royal Society of Medicine, and the Vice-Chancellor of the University of London, and to others interested in the sister departments of practice. It was attended by many guests and a large contingent of provincial members, who remained on in London for the meeting of the Section of Otolaryngology the following day and the Section of Otolaryngology later. The meeting room of the Royal Society of Medicine was completely filled at these gatherings, and the extra-metropolitan members expressed warm appreciation of the arrangements made to enable them to attend three such interesting gatherings during one visit to London. The cultivation of the social side of the work of the two Sections also helps to explain their activity, and the existence of a most admirable camaraderie. The Central Throat Hospital held its annual dinner under the chairmanship of Dr. Dan McKenzie on one of the evenings mentioned, and the Presidents of the two Sections (Dr. Banks-Davis and Mr. Sydney Scott) entertained the Councils, the Semon orator, and Professor Burger of Amsterdam. The latter is an honorary member of the Section of Laryngology, and well known here as permanent secretary of the International Congresses of Medicine. He largely helped in the success of the last, that held in London in 1913.

#### INCIDENCE AND CAUSE OF HERNIA.

SIR ARTHUR KEITH devoted the Banks Memorial Lecture, which he gave before the University of Liverpool last week (as noted elsewhere), to the subject of the origin and nature of hernial formation. The full text of the lecture will, we understand, be published in the *British Journal of Surgery*, and we will confine ourselves here to a short account of its general argument. The lecturer began by dealing with the incidence of hernia, and observed that a great deal had been learnt about it through the very large number of physical examinations of men made during the severe recruiting for the war. Such examinations revealed the fact that among males of 18 to 41 in the South of Scotland, 36 per 1,000 suffered from hernia. In various parts of England and the ratio was 10 per 1,000, and in the neighbourhood of Manchester and Stockport it was 50. Taking males at all stages of life he thought it probable that about 20 per 1,000 would be found to be suffering from hernia, but that in females, excluding pelvic protrusions, the ratio was 3 to 4 per 1,000 only. He alluded to the work of Ruskon Parker, who, after the introduction of Listerian methods, was a pioneer in performing the operation for radical cure. The two theories of the cause of hernia held by various surgeons were then discussed. The one school considered that developmental defect was the prime cause, and held that no rupture occurred unless there was a preformed sac into which the protrusion could take place. The other school, to which Banks belonged, maintained that the protrusions and simultaneous formation of peritoneal pockets or sacs might be formed either before or after birth. The cases in which the surgeon was confronted in adult life were provisions into sacs formed at the same period that the hernia developed. Sir Arthur Keith then dealt in detail

with the descent of the testicle into the scrotum, and compared it to a severe operation that in some cases left the muscular abdominal wall weak. That other mammals did not suffer to anything like the same extent as the human infant was due to the much more efficient muscular arrangement in them than in the baby's groin. He thought that the efficient working of the muscular guard of the breach in the groin depended on the state of the bowels and other conditions over which medical men could exercise control. Before attributing to imperfect evolution a baby's liability to hernia, it would be well to explore first the possible mistakes we might be making in our nursing and treatment of infants. In adult life sudden muscular effort unmasks a latent hernia. Unfortunately we had no facts to guide us in deciding how far special occupations, involving particular movements and abnormal positions of the body, might influence the production of latent hernia. Further and exact observations were urgently wanted to elucidate the causes and conditions of what might be termed vocational ruptures.

#### FUMIGATION BY HYDROGEN CYANIDE.

RESEARCHES by hydrogen cyanide for the destruction of rats and insects was discussed a short time ago (September 22nd, p. 527) in a review of an article by Colonel Glen Liston, I.M.S., and we then described some of the precautions which are of importance. The Ministry of Health has now issued a preliminary report on the subject, with a prefatory note by Sir George Newman, who explains that the investigations described were commenced under the supervision of Dr. Richard J. Reece, the senior medical officer of the branch of the Ministry's Medical Department which is concerned with port sanitary administration, and that the inquiries were made by Dr. P. G. Stocks, one of the Ministry's medical officers, in association with Dr. G. W. Monier-Williams, one of the Ministry's chemical experts, who during the war had been specially engaged in the anti-gas section of the British Army in France. Dr. Reece and Dr. Stocks visited the United States to study the method of cyanide fumigation employed in the ports of that country, and Dr. Stocks also made inquiries on the subject in Holland and other European countries. The present preliminary report has been prepared by Drs. Stock and Monier-Williams "in order that the knowledge and experience so far acquired concerning hydrogen cyanide might be available to all who are directly or indirectly concerned with the use of the gas as a fumigant. The scientific and practical results and conclusions it contains appear to be entirely correct, and Colonel Glen Liston in India to design cyanide fumigators which would minimize the dangers inherent in the so-called "dumpling process." It seems clear that whatever precautionary rules and regulations may be made, safety to the lives of persons engaged in cyanide fumigation on board ship cannot be ensured except by using a fumigating machine scientifically designed with full knowledge of the difficulties and dangers to be overcome. The advantages of hydrogen cyanide gas, the methods of generating it, its properties, the chemical and other tests of its presence, the fumigation and subsequent ventilation of a ship, the accidents that have happened and the precautions that ought to be observed, are all dealt with in the report, which is illustrated with diagrams and photographs, and includes prints of the Johannesburg by-laws regarding the trade of disinfection by cyanide, of a circular to masters and agents of vessels.

Ministry of Health Reports on Public Health and Medical Subjects. Fumigation Report on the use of Hydrogen Cyanide for the destruction of rats and insects. By P. G. Stocks, M.B., and G. W. Monier-Williams, M.B., Ph.D., F.R.C. Published by H.M. Stationery Office, 1923. Price 2s. 6d. net.

one immediately after operation; the highest mortality occurred amongst the high abdominal cases. As a rule Dr. Featherstone gave gas and oxygen when the effects of the drug were beginning to wear off, and in cases where the Trendelenburg position was needed. Occasionally a little ether might have to be added.

In regard to the site of operation, those needed above the colon were best carried out under general anaesthesia. Patients with adhesions of the small intestine showed more distress than those in whom such adhesions were absent. Pulling on the intestines might cause vomiting and even pain, though the patient was usually unable to localize this. Stimulation of the diaphragm caused distress unless the cervical cord was anaesthetized. The action of the lumbar analgesia on the pregnant uterus was of great interest. There was tonic contraction of the body and cervix, though the circular fibres alone seemed to take part in this. Pain was absent and loss of blood slight. The progress of the foetus downwards was slow until the drug began to wear off and the longitudinal fibres started to contract. Then the child could be readily and painlessly expressed, and if necessary the placenta also. The pain sensation was the last to be recovered. On the other hand, dilatation of the non-pregnant uterus became increasingly difficult, as the cervix tended to contract after each instrument was passed.

The drug caused a fall of blood pressure; the minimal fall recorded by the author was 15 mm., the maximal 70 mm., but this last was probably due to the table being tilted too quickly. Post-operative treatment consisted in keeping the bed horizontal, with the patient's head on pillows, and the legs well raised. Immediate untoward after-effects were extremely rare. Remote after-effects showed headache in 40 per cent., and giddiness in the enfeebled cases. Of the 40 cases with headache 39 were women.

The author's conclusions were as follows: (1) Patients suffering from diseases of lungs, heart, kidneys, chronic toxæmia and diseases of metabolism may well be treated by intrathecal methods. (2) The presence of acute traumatic shock is a contraindication. (3) The method does not prevent abdominal shock associated with severe handling of a viscus above the colon without very high paralysis. (4) Exhaustion from manipulation of the pregnant uterus in labour and of the pelvic organs in general is rarely seen. (5) Association with light general narcosis is most helpful. (6) Early post-operative headache rarely occurs with tropacocaine, provided that there is little loss of cerebro-spinal fluid. (7) The most careful handling of these cases is needed if a considerable fall in the blood pressure is to be avoided. (8) Late complications attributable to the spinal anaesthetic are extremely uncommon in the absence of infection.

#### Discussion.

Mr. H. BECKWITH WHITEHOUSE was of opinion that surgeons who gave their own spinal injections had wandered into the domain of the anaesthetist. He believed in team work, and that necessitated the employment by the surgeon of an anaesthetist whom he could trust and who was familiar with the surgeon's idiosyncrasies. He had no doubt that in all operations on the pregnant uterus the employment of tropacocaine by the spinal route practically eliminated haemorrhage. He also had noted that his results were better since he had employed the drug in Wertheim's operations, in large resections of the vulva in old women for such diseases as leucoplakia, and in cases of pregnancy with advanced cardiac disease. The contraindications were obesity, pelvic inflammation, normal labour, and certain conditions of abnormal labour where such proceedings as version were required.

Dr. F. E. SHIRWAY questioned whether the results obtained in war surgery really showed the unsuitability of spinal analgesia in cases of shock. Work during the war was for the most part hurried, and too large doses were apt to be given with the mistaken idea of hurrying the onset of anaesthesia. He suggested that Dr. Featherstone's doses were very large, and, as the result of his own experience with stavaine, advised him to try the effects of a smaller dose. He then showed on the epidiascope diagrams taken from actual cases illustrating the smaller fall in blood pressure where smaller doses of the drug were given. He usually administered small doses of a C.E. mixture along with the spinal injection. In cases of prostatic resection in old men, he found the combined spinal and inhalation method very satisfactory.

Dr. R. E. APPERLY said that the patient ought to be kept in the Trendelenburg position until the effect of the spinal injection had worn off. Such was his practice with hospital cases, but in private it was more difficult to ensure this being done and it was often necessary to devise expedients to that end.

Dr. C. F. HADFIELD inquired why Dr. Featherstone used tropacocaine. He thought spinal injections should be made under scopolamine-morphine narcosis. To illustrate how easy it was for false deductions to be made, he mentioned a case in which, while the surgeon was dissecting out a large malignant growth of the bladder, the effect of the spinal injection wore off, and he was forced to continue with a little chloroform. Bleeding became more profuse, and he was promptly reprimanded by the surgeon for using ether! One of the drawbacks of spinal analgesia was the tendency of certain patients to retch and vomit after the drug had been administered. As a rule this passed off quickly, but it was a distinct hindrance to the surgeon if it occurred while the operation was in progress, owing to the violent extrusion of the bowels from the wound while the abdominal walls were in a state of complete relaxation. So far as the uterine muscle was concerned he had not been able to notice any difference, as regards bleeding, between the effects of a spinal injection and of a general anaesthetic. His experience of the duration of a spinal anaesthetic was that the analgesia lasted on an average forty minutes, but in certain cases it might be prolonged to one and a half hours.

Dr. HUGH PHILLIPS said that he refused to give a spinal injection without a preliminary general anaesthetic in small amount. His experience of the onset of headache after such injection was the opposite of that of Dr. Featherstone, with regard to the amount of fluid drawn off. He found scopolamine-morphine distinctly useful when dealing with women but unreliable in men. As regards children spinal injections after an extensive trial had been given up at Great Ormond Street. In parturition there was a difficulty in removing the placenta after a spinal injection.

Dr. C. H. M. HUGHES had had two deaths in diabetic patients following the use of a heavy stavaine solution. He had since used a lighter solution with better results in such cases. He attributed the high percentage of headaches in Dr. Featherstone's cases to the fact that no general anaesthetic was given. He believed that a C.E. mixture ensured the most tranquil anaesthesia and he administered it after the injection had been given. He believed also that heavy solutions were apt to cause headaches, for he had had no such complaints since he had taken to using lighter solutions.

Dr. W. J. MCCABE said that vomiting and collapse during spinal analgesia were often the result of the surgeon pulling on the small intestine. He did not think that the contraindications to spinal analgesia were sufficiently emphasized by the opener of the discussion. These consisted chiefly in the presence of myocardial disease and low blood pressure. His experience was that tropacocaine was less toxic than stavaine.

Dr. L. K. THOMAS questioned, at the risk of being dubbed unpatriotic, whether the tropacocaine now used in this country was as powerful and as certain in its effects as that of German origin used before the war. He did not find a general anaesthetic necessary before the insertion of the needle. All that was necessary was to numb the skin with the ethyl chloride spray, and it could then be painlessly incised with a sharp-pointed bistoury, and the needle inserted without inconvenience to the patient.

Dr. FEATHERSTONE, in reply, said that he used tropacocaine in all the cases of this series as he wished to compare his results after carrying out a uniform method of injection. He found this drug very satisfactory. So far from believing the English preparation unreliable, he quoted an authority who had used the German preparation extensively before the war, and had found that the ampoules dispatched from the German factory varied not only in the quantity of the solution contained in the ampoule, but also in the strength of the solution; and it was to overcome these defects that the authority in question prevailed upon a British firm to undertake the preparation of the drug as now used. He then replied seriatim to the points raised by the various speakers.

regarding fumigation at the port of New York, and an outline of the routine adopted for fumigation of ships there, as well as a note on a cyanogen chloride gas mixture used in the United States. Australian apparatus is described, and notes are given on first-aid treatment of cyanide poisoning. The report leaves no room for doubt either as to the efficiency of fumigation by hydrogen cyanide for the destruction of rats and vermin, or as to the danger to the lives of persons engaged in fumigation when carried out with the more or less crude appliances usually employed. Sir George Newman in his preliminary note expresses the opinion that the procedure must be classed as a hazardous occupation, and raises the question whether the application of the method should be specially restricted by licence. The law of diffusion of gases and the experiments of Graham and Loschmidt referred to in the report point to the conclusion that the complete mixing of two gases by diffusion is a matter, not of minutes, but of hours. Analysis of samples of gas taken in different parts of a ship at various times during fumigation indicated that the diffusion of the gas may be incomplete, and that, for thorough fumigation of large spaces it may be necessary either to increase the number of points at which the gas is generated or to arrange for artificial circulation of the gas. "As gaseous diffusion is slow, the clearing of a ship from gas must depend almost entirely upon the movement of air currents in the manner of ordinary ventilation, the atmosphere of the ship being regarded, not as gas, but as poisoned air. In certain circumstances it might be very difficult to clear the gas by natural ventilation without the use of fans, and pockets of gas might remain for many hours or even days in the lower parts of the ship. These considerations are of fundamental importance. It is absolutely necessary to test systematically the progress of ventilation by means of rats or in other reliable ways, and it is dangerous to assume that a certain number of hours is sufficient for clearing under all conditions. The report contains interesting sections on the biological action of the gas on animals and on its detection by physical, chemical, and animal means; the discussions of the biological action on birds and of the chemical tests for the presence of the gas do not seem fully to cover the literature of the subject, and the same criticism is applicable to some other items of information; such omissions, however, are perhaps unavoidable in a report of a preliminary nature. A great part of it is concerned with elaborate details of the precautions necessary to be taken before, during, and after fumigation. They are doubtless necessary when the "dumping method" is used, but it is possible that the emphasis laid upon them may arouse opposition to a very useful and efficient method of disinfection which has been carried out with a satisfactory apparatus operated by an instructed personnel.

# MEDICAL INCUNABULA.

The great medical library of the College of Physicians of Philadelphia has just issued a *Catalogue of the Incunabula* in its possession. A catalogue of this series appeared in the *Annals of Medical History* some time ago, but since then many valuable incunabula have been added, and now we have a complete descriptive catalogue of all that the Philadelphia library contains of books of that class. The incunabula (books printed before 1500) in the library now number 337, and it is safe to say that no medical library in this country can lay claim to such an extensive collection. The College of Physicians of London possesses 110, but they are not all medical, and smaller numbers are to be found in the libraries of the College of Surgeons and the Royal Society of Medicine. If collected

tions of this class of book are to be made the necessary funds must be forthcoming, and unfortunately few of our medical libraries possess sufficient money for this expensive but very laudable form of book-collecting. Occasionally a stroke of good fortune places in the possession of a library a valuable collection, such as the magnificent bequest of the late Dr. Lloyd Roberts, who in his will left to the library of the Royal College of Physicians of London over 2,000 books, of which more than fifty were incunabula. This may be regarded as an example of the way in which our medical libraries may be enriched, and is wholly worthy of emulation. The catalogue before us is compiled in a most careful and complete manner, and, conforming to Hain, contains all the information necessary for the bibliographer. We congratulate Mr. Charles Perry Fisher, the librarian, on the way in which he has accomplished his task.

## FACTORS DETERMINING BACTERIAL VIRULENCE.

It is certain of the reports from the pathological laboratory of the Ministry of Health—as, for example, in those dealing with the complement fixation test in syphilis and bacteriological studies on the pneumococcus—the authors, in addition to presenting their own researches, have undertaken a comprehensive survey of the literature of the subject, and passed in review rival theories and opposing hypotheses, commenting on their merits or indicating their deficiencies. Such general discussions have great value. A bacteriological problem is often attacked by different research workers from different points of departure: they may be armed with different weapons of technique, their aim directed at different objectives and inspired by different plans of campaign. An "eye witness" of the different parts of a particular problem is more competent to adjudicate on the issue and may provide a narrative of historical value, of general interest to all and fertile in suggestions for future policy. In his essay on "Factors determining bacterial virulence," which forms part of one of the recent publications of the Ministry of Health,<sup>1</sup> Dr. Eastwood has recorded no researches of his own, but has provided a dissertation on a problem of immunity which has provoked considerable controversy in the past. The periodic fluctuations in bacterial virulence which to some extent may be responsible for the rise and decline of epidemics, the peculiar immunity of certain species of animals to bacteria highly virulent to other species, the mysterious impulse in obedience to which the normally harmless saprophytes of the human body invade and penetrate the mucous membranes, have not hitherto been satisfactorily explained by the antigen-antibody theories of immunologists. The most refined serological tests have failed to discriminate between the bacterial structure of virulent and non-virulent members of the same bacterial species. "Habit of growth" provides no explanation, for saprophytes may, without apparent reason, swiftly strike and swarm through vital tissues, on the surface of which their innocuous existence has long been tolerated. The presence of some adjunct may be necessary to permit bacteria to invade the tissues and become pathogenic. This is no new conception, and in his report Dr. Eastwood recalls evidence which bears on this question, made—there is insufficient unanimity of opinion—but one directly and indirectly. No positive assertions can be line of thought has led him to the following hypotheses. It may be assumed that an important distinction between a virulent and a non-virulent strain of bacteria lies in the fact that the former interacts with its animal host in such a way as to produce an environment favourable to bacterial growth within the tissues, whereas the latter fails to do so.

## ANCIENT CHINESE MEDICINE.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on October 26th, with Dr. R. J. REECE, the President, in the chair, Dr. W. PERCEVAL YETTS read a paper entitled "Pestilence and leechcraft in ancient China." He discussed a period stretching from 5,000 years ago down to the third century of our era. The beginnings of Chinese medicine, he said, went back far beyond the range of authentic history. Accordingly Dr. Yetts, without attempting to sift fact from myth and legend, gave the current traditions attributing the art of healing, like other fundamental achievements of civilization, to the three great culture-heroes of the race—the Emperors Fu Hsi, Shên Nung, and Huang Ti. He next read a translation of the opening passage of what was probably the oldest medical treatise extant in China. Therein the chief medical adviser of Huang Ti deplored the general physical and moral decadence of society as it existed more than twenty-six centuries B.C. Dr. Yetts went on to describe the elaborate State medical service under the Chou dynasty, which flourished for eight and a half hundred years from the twelfth century B.C. An interesting circumstance was the use by the Chinese at those remote times of antiseptics for the treatment of infected wounds. The account included two other government departments concerned with preserving the public health of ancient China. They comprised the court wizards and the court exorcists; and it was shown that their successors still, after some 3,000 years, function as protectors against the demons of disease. The standard of qualification and the status of medical men were next discussed. Apprenticeship and the acquisition of approved prescriptions were the recognized methods of preparing for professional practice. The status then was no better than in less ancient times. In the Chou period doctors were classed with a number of others "who professed particular arts for the service of their superiors." The list ran as follows: "Prayer-makers, writers, archers, carriage-drivers, doctors, diviners, and artisans." The earliest undoubted mention of an epidemic referred to one which occurred in B.C. 243; it did not specify the nature of the disease. Some famous doctors of antiquity were next passed in review. There was a legend of an operation performed under an anaesthetic as early as the fifth century B.C., and a more authentic account of a similar event is assigned to the third century A.D. Probably hemp was the drug. After speaking of methods of diagnosis, Dr. Yetts outlined forms of treatment under the headings drugs, diet, acupuncture, and physical exercises. The paper ended with a few words about the bibliography of ancient medical literature in China. The paper was illustrated with lantern slides.

A discussion followed in which the PRESIDENT, the CHINESE MINISTER, Dr. CULPIN, Dr. J. C. McVAIL, Sir DENISON ROSS, Dr. MAJOR GREENWOOD, Dr. LEE, and Fleet Surgeon W. E. HOME took part.

TREATMENT OF LATE NEURO-SYPHILIS AND  
DISSEMINATED SCLEROSIS.

A MEETING of the Liverpool Medical Institution was held on October 25th, with the President, Dr. J. HILL ABRAM, in the chair, when Dr. A. C. RANSOME read a paper on the treatment of late neuro-syphilis and disseminated sclerosis.

Dr. Ransome gave the results of his treatment of those two classes of organic nervous diseases in Manor Hill Neurological Hospital. Cases of tabes, tabo-paresis, and early general paralysis of the insane were divided into two groups for treatment according to the condition of the cerebro-spinal fluid. Those with a high cell count, a tabo-paretic gold curve, an excess of globulin, and a positive Wassermann reaction were given intrathecal injection of reinforced salvarsanized serum, while those with a luetic gold curve, a lower cell count and globulin excess, and a positive Wassermann reaction were given neo-kharsivan or mercury oxy-cyanide by intravenous injection. Both groups received the same after-treatment of mercury and potassium iodide by the mouth. The clinical results of treatment agreed very closely with the effects on the condition of the cerebro-spinal

fluid. In this the reduction of lymphocytes and of globulin and the flattening out of the gold curve were very marked, and were accompanied by the cessation of pains and crises, by increased control of sphincters, and in some cases by ability to return to work. Lantern slides were shown illustrating the condition of cases before treatment, after treatment, and after an interval of a year.

The reports of thirteen cases treated by intrathecal salvarsanized serum showed that 8 had improved, in 3 there was no change, one was worse, and one case was transferred. Twenty-six cases treated by intravenous neo-kharsivan and mercury oxy-cyanide showed 9 improved, in 11 no change, and 6 left hospital. Thus intrathecal treatment appeared to be more efficacious than intravenous, in spite of the fact that the former group were more advanced clinically and pathologically. Thirty-six cases of disseminated sclerosis were treated by intravenous injection of silver salvarsan on the assumption that the disease was caused by a specific spirochaete distinct from that causing syphilis. The results were: 14 improved, in 10 no change (including 5 only recently treated), 9 left hospital, and 3 died of intercurrent disease. While allowing for errors of observation, possible remissions, for the concomitant effects of massage, exercises, healthy surroundings, etc., Dr. Ransome considered that the result of this treatment was encouraging and worthy of further trial.

Dr. DOUGLAS BIGLAND thought that too much weight had been placed upon the colloid gold reaction, which was notoriously unreliable on occasions. This test was most useful when it agreed exactly with the other spinal fluid reactions. While agreeing that good results might be obtained from intrathecal therapy, yet he had obtained just as good effects with drugs administered by the intravenous and oral routes. He considered that when two methods of treatment gave approximately equal results the simpler, the less expensive, the less painful, and the more generally applicable one should be used in preference to the one which had not those advantages. In his opinion the effects of mercury, especially when administered by injection, were little short of marvellous in certain forms of neuro-syphilis.

Dr. BAKER YOUNG said that the advocates of intrathecal therapy claimed that advanced cases of neuro-syphilis could be benefited and in some cases enabled to return to work, while in others the improvement would allow them to resume home life. Cases in which a paretic curve with the gold sol was persistent, in spite of treatment, were invariably fatal and particularly prone to suicide. Intrathecal therapy was indicated in early cases which showed an abnormal fluid. Fordyce said that at least 25 per cent. showed changes even after intensive treatment intravenously. If those cases were then treated intrathecally the fluid became normal and the natural inference was that a potential tabetic or paretic finale had been avoided.

*Dextrocardia.*

Dr. JOHN HAY and Dr. H. WALLACE JONES read a note on dextrocardia. Dr. Wallace Jones said that the term "dextrocardia" in its widest sense was applied to a heart beating in a more or less permanent manner in the right half of the thorax. The condition had been known from ancient times, but the modern application of the x rays and electro-cardiograph had made the diagnosis one of comparative ease. He classified the varieties as follows:

1. Inversions ("mirror image" of the heart). (a) Complete. (b) Incomplete: (1) Transposition of viscera with heart in the normal position. (2) Complete inversion of the thoracic organs, and the liver situated in the middle line. (3) Inversion of the heart only.
2. Dextro-versions (heart displaced to the right without inversion of the cavities). (a) Occurring during foetal life. (b) Acquired since birth.

He showed records of four cases, two cases of complete transposition with inversion of the main deflections in lead I of the electro-cardiograph, and two cases of acquired dextrocardia not due to any obvious cause, with normal electro-cardiograph records.

*Syngomyelia.*

Dr. T. W. WADSWORTH read a note on a case of syngomyelia—a patient who died, aged 51, from a pontine haemorrhage. On post-mortem examination there was an extensive

These products of interaction between bacterium and host are antigenic, as can be shown by using for immunization the sterile exudate from a fatally infected animal, but of purely bacterial antigens and give rise to different antibodies. The struggle between bacterium and host may be regarded as depending on the balance between the output of (1) material which favours bacterial growth, and also acts antigenically, and the output of (2) antibody, which means restriction of bacterial growth and consequently protection for the host. The foundations of this hypothesis are that when bacteria grow in animal tissues special substances are formed resulting in an environment favourable to further bacterial growth; that these special substances act antigenically, and against them the host may manufacture special antibodies. Let it should be suspected that we are now being introduced to yet another new antibody, of which the number already taxes the memory of the most erudite immunologists, it may be pointed out that the conception of these substances has many resemblances to that of "aggressins" and "ant-aggressins." Dr. Maswood has found support for his hypothesis from an analysis of the work of many schools of research.

THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH.

The South African Institute for Medical Research at Johannesburg has a research division and a routine division. The cost of the research division is met by contributions of equal amount from the Union Government and the Witwatersrand Native Labour Association; the routine division is maintained out of the revenue earned from services rendered for payment and from the sale of vaccines and sera. The annual report of the institute for the year ending December 31st, 1922, states that the cost of maintenance of the research division accounted for £9,944, and the routine division £17,272, but the total revenue of this division was £18,993. Some of the main activities of the research division of the institute are concerned with the following diseases: Epidemic meningococcal, meningitis was prevalent on the Witwatersrand from June to September, affecting more especially several of the mining compounds, but also to some extent the general population, both white and coloured. In August the monthly death rate per 1,000 from meningitis amongst the native labourers rose to 0.32, the highest rate hitherto recorded. Forty-eight strains of the meningococcus were obtained from the cerebro-spinal fluid of three European and forty-five African native patients, but twenty-nine of these strains did not belong to any of Gordon's four types. In South Africa there appears to be a rising incidence of infections due to aberrant strains, a fact of some importance since this alteration of types has a direct bearing on the efficiency of anti-meningococcal serum, and complicates its production for general use. A ready method for preserving the stability of the meningococcus for transmission in culture to other laboratories has been devised; the while of a twenty-four hour growth of meningococci from a blood agar slant is planted into a tube of heated ("chocolate") human blood agar whilst the latter is still liquid at a temperature of 40° C. In order to test the possibility of controlling the incidence of cerebro-spinal meningitis amongst native mine labourers by means of prophylactic inoculation twenty-four were inoculated—eighteen subcutaneously and six intramuscularly—with a meningococcus vaccine. The blood serums of these cases were repeatedly tested for the presence of agglutinins, but in no instance

could a trace of agglutination be detected. This entirely negative result does not, of course, preclude the possibility of some immunity having been produced. An outbreak of epidemic influenza which occurred in Johannesburg and the Transvaal afforded an opportunity for search for a filter-passing virus. Naso-pharyngeal washings in normal saline were taken from fifteen patients, in eleven instances within twenty-four hours of the onset of the disease. The washings were passed through filter candles and the filtrates cultured anaerobically in Smith-Noguchi medium. After a period of six to eight days, in the tubes from five of the cases, minute bodies were observed in enormous numbers. Stained films from these were subsequently sent to Dr. Mervyn Gordon and he has advised the institute that the minute bodies therein are indistinguishable from those cultured and described by him. Attempts were made to infect human beings with the filter-passing organisms, nineteen individuals volunteering for the experiment. A definite attack of influenza occurred in one individual, the temperature rose to 100° F. or over in two others, with a definite leucopenia in one of them. As the report remarks: "The results obtained in this experiment are by no means sufficiently conclusive to incriminate unequivocally this filter-passing organism as the cause of influenza," although they provide encouragement to persevere with this line of research. An investigation has been undertaken into the effect of freezing on the vitality of the cysts of tapeworms found in "meats" of beef and pork. A temperature ranging from -6° C. to -18° C. for a period of about ten weeks is necessary to destroy the vitality of all the cysticerci in carcasses of beef and pork. For safety a margin should be allowed in this period of freezing, and it is suggested that slightly infected beef or pork must be frozen for at least twelve weeks before the meat may be regarded as sterile with respect to cysticerci. The freezing of meat for human consumption at such a low temperature and for such prolonged periods interferes with the nutritive value and subsequent keeping properties of the meat, so that when a carcass is heavily infected it should not be used for human food even after freezing for twelve weeks. These are but three of the many different researches undertaken by workers at the institute during 1922 of which an account is given in the report. The remainder of the report is concerned with the work of the routine division. The total number of investigations carried out during the year was 27,439, an increase of 4,247 on the number for 1921, and three times the figure for 1914, the first year of the institute. All kinds of bacteriological, chemical, and histological examinations are undertaken by the institute. The total number of autogenous vaccines prepared during the year 1922 was 758, and the amount of stock vaccines prepared and issued to store totalled to a volume of more than half a million cubic centimetres!

THE ENERGY OF THE ATOM.

In his presidential address to the Röntgen Society on November 6th Sir Oliver Lodge took for his subject "X rays and the atom." It was, he said, now quite clear that inside the atom there were definite energy levels—a kind of staircase—at any of which the electrons could rest or revolve in stable equilibrium. When occasion arose an electron could drop from one level to another within the atom and thereby emit a characteristic radiation or spectrum. Why there should be these energy levels, or intervals of stability, no one had yet attempted to explain, and in the absence of explanation it was justifiable to make surmises. He supposed that the nucleus of the atom was in a state of violent rotation about its axis, that the state of circulation in that neighbourhood was comparable with the velocity of light. He even went so far as to assume that the normal ether contained a constituent

gliosis of the central region of the cord extending from the upper cervical cord to the lumbar region. In the cervical and mid-dorsal regions there were large cavities near the central canal, not lined by ependyma. The patient had manifested symptoms of syringomyelia for over twenty years, and carried on his occupation as a labourer up to three years of the time of his death. His hands were claw-like, with many scars, due to old painless injuries and burns, some of the latter being recent; tactile sensation was almost normal, but there was loss of sensation to heat, cold, and pain, especially of the hand. There was well marked scoliosis and spasticity of the legs; towards the end he became ataxic. No arthropathy, perforating ulcer, nor nystagmus was present.

### DISSEMINATED SCLEROSIS.

THE Royal Medico-Chirurgical Society of Glasgow met on October 18th, with the President, Dr. MAITLAND RAMSAY, in the chair, when a discussion was held on the pathology, symptomatology, and treatment of disseminated sclerosis.

Dr. DOUGLAS ADAMS in an opening paper briefly reviewed the literature of disseminated sclerosis, and referred more particularly to recent results obtained in an investigation which was being carried out in the Pathological Department of the University and Western Infirmary of Glasgow in collaboration with Drs. E. M. Dunlop, J. W. S. Blacklock, and J. A. W. McCluskie. In a considerable number of cases paralysis had been transmitted to rabbits by the injection of blood or spinal fluid from patients suffering from the disease, and had been passed from rabbit to rabbit, both by direct inoculation and by passage through culture. Spirochaetes were found in the organs of seven of the inoculated animals both by dark ground examination and by staining, though examination of the cultures employed yielded negative results. These results were regarded as confirming the view that the disease was infective in origin. Emphasis was laid on the necessity for early diagnosis, and in this connexion the value of the colloidal gold reaction was urged. The results of intensive antispecific treatment of fifty cases were referred to. In many cases considerable clinical improvement had been noted and this had coincided with a modification of the colloidal gold curve in a negative direction. In the majority of cases the subsequent absolute or relative freedom from relapses during a period of three years was striking. The investigation was being continued under a grant from the Medical Research Council.

Dr. J. W. S. BLACKLOCK described in more detail the various experiments performed, and said that when blood or spinal fluid from cases of disseminated sclerosis had been inoculated directly into rabbits about one-third of the animals developed nervous symptoms. Emulsion of the central nervous system of these paralysed animals produced nervous symptoms in a proportion of cases on inoculation into other animals either directly or after passage through Noguchi's medium. No nervous symptoms had been noted in over 200 normal control animals kept under observation for periods varying from four months to over a year, nor had paralysis developed in animals inoculated with various protein substances. He considered it probable that a virus was present in the blood and cerebro-spinal fluid of these patients which was capable of existing in the central nervous system and of producing paralysis in a proportion of the animals inoculated. The pathological lesions that had been noted in the central nervous system of the inoculated animals were: (1) Cellular infiltration, chiefly under the ependyma of the ventricles. (2) Degeneration of nerve tracts—this had been observed only in one animal which had lived for over a year after the onset of paralysis; the other animals which had shown nervous symptoms had lived for too short a time after the onset of such symptoms to allow definite pathological changes to occur. (3) Petechial haemorrhages. (4) Multiple lesions of the nature of softening.

Dr. BROWNLOW RIDDELL referred to the frequent occurrence of slight and transient eye symptoms in the early stages of the disease, and urged the importance of a critical interpretation of such symptoms in a case presenting no other apparent clinical feature. The surprisingly slight

attention paid by the average patient to transient eye symptoms, with the speedy recovery therefrom, and the absence of any other sign or symptom, combined to present a clinical picture often underestimated or attributed to a functional, hysterical, or digestive origin. Dr. RiddeLL then discussed in detail the various symptoms, including diplopia, acute retrobulbar neuritis, nystagmus, and optic atrophy, and described a number of illustrative cases.

Professor C. H. BROWNING, in commenting on the results of the experimental work, said that the small proportion of successful transmissions was not surprising in view of the insusceptibility of both man and animals to the disease. He emphasized the fact that the virus persisted in the culture media which had been inoculated with blood from cases and kept over long periods in the incubator, and was inclined to the opinion that the pathogenic agent was a living organism or the product thereof. He then referred to the value of the colloidal gold reaction as a means of early diagnosis and of controlling the results of treatment.

Professor ROBERT MUIR, in referring to the pathological and histological changes in the disease, said that while they were very definite they yet presented certain peculiar characteristics. The essential features at an early stage were (a) a disappearance of the myelin sheaths, (b) a persistence of the axis cylinders, and (c) an absence of Wallerian degeneration. These changes occurred in patches which were often sharply cut off, as though by a knife, from the surrounding healthy tissues. The process was peculiar and quite unlike a true sclerosis. The colloidal gold reaction in the cerebro-spinal fluid he considered would mark a real advance, if completely established, and would prove of great assistance in controlling treatment. Referring to the etiology, he was of the opinion that, while a great many facts supported the infective theory, the state of the experimental work was as yet too uncertain for complete proof. While hopeful, it was not conclusive.

THE annual meeting of the West Kent Medico-Chirurgical Society was held on October 12th at the Miller General Hospital, Greenwich, when Dr. W. H. PARRY, the retiring president, vacated the chair to Dr. E. G. ANNIS, M.O.H. for Greenwich. Mr. C. A. JOLL showed two specimens of carcinoma of the rectum: (1) from a woman aged 65, who suffered from mucous stools, tenesmus, and haemorrhage, and (2) from a man, aged 64, who suffered from pain and diarrhoea; he also reported a case of fibro-sarcoma of the thigh muscle, without any glandular involvement, the tumour being an encapsulated cyst. Dr. H. PRITCHARD showed a young woman, aged 24, who developed a streptococcal empyema fourteen days after childbirth; an abscess developed in the left buttock; the lung was not involved. He pointed out the rarity of a primary streptococcal pleurisy. The case was treated by opening, drainage, and antistreptococcal serum. Dr. M. DAVIDSON showed a case of pernicious anaemia, with blood and nerve lesions. Injections of iron cacodylate were given, and also arsenic by the mouth.

A MEETING of the Bath Clinical Society was held at the Royal United Hospital on October 5th, with Dr. W. P. KENNEDY, President, in the chair, when Dr. R. G. GORDON read a paper on the "Difficult Child." He dealt with the types of difficult behaviour in children both in infancy and in later life. The importance of the attitude of the parent was emphasized. The causes of failure of integration of the personality leading to difficulty in adaptation to life were classified under three headings in relation to the proper functioning of the cortex: (1) Failure of development—mental deficiency; (2) disease of the cortex, especially congenital syphilis and epidemic encephalitis; (3) inherent lack of proportion in dispositions leading to psychological maladaptations. Illustrative cases were described. Dr. R. WATERHOUSE showed a case of anterior poliomyelitis with a meningitic origin. Mr. A. L. FULLER showed a case of webbed fingers treated by a graft from the thigh. Mr. J. S. LEVIS showed three specimens—one of hydronephrosis due to a calculus blocking the ureter, the second a heart showing four active valves, and the third an epithelioma of the liver. Mr. A. L. FULLER showed a specimen of a gall bladder, shrivelled and partly calcareous, the size of a pea, and a gall stone the size of a walnut, removed from the common duct in the same patient.

tional rotation, and that upon this, when a pair of electric units were being somewhat generated, two equal opposite rotations were superposed, one in opposition to the original rotation, giving a net result of zero, and the other in the same direction, accelerating the velocity. In any case it might readily be granted that around the nucleus there was an ethereal circulation essential to the existence and behaviour of the nucleus, very intense close to the nucleus and decreasing with distance, according to some vortex or etheric law. This whirl might be stratified; it might continually decrease in speed as distance from the centre increased, and its strata might be described as gravitational or electrical levels. If an electron entering the whirl found itself on one of those levels it could be carried forward by the fluid at that place in a state which satisfied its own requirements. It could abandon itself passively to the fluid of which it was a part, and be not only in equilibrium but at rest. Thus there might be within the atom a permanent circular orbit free from radiation and quite stable until some disturbance occurred. Such a level might be expected at regular intervals whenever the vortex velocity and the attracted electronic velocity had the same value. At the intermediate places there would be no equilibrium, and there the electron would either fly out or fly in according to the circumstances of its propulsion. A particle either entering the atom from outside or being precipitated from one orbit into another within the atom would, starting from radial rest, arrive at any given stratum at an excess speed. It might puncture the stratum and go on, but if it were held it could only be held by overshooting the mark and being brought back again, so that it would perform a series of isochronous oscillations, while its radial energy was being converted, part of it into tangential energy and part into radiation. The restoring force at any point would depend on the speed of the whirl there, and would naturally be more vigorous as the centre was approached. He gave some reasons for supposing that the frequency of this oscillation would be proportional to the energy to be radiated, and that the radiation of energy would be as the square of the restoring force. It might be said, he concluded, that this was shoddy *ad hoc* reasoning, whereby assumptions were made to explain other assumptions, but the physics of the present century had been so full of assumptions that a few more might be permissible, especially those made with the ultimate object of reducing their number. In response to a vote of thanks, Sir Oliver spoke further of the vast progress in physics of recent years. In physics anything five years old was ancient history. This had been a remarkable quarter of a century, and if the work continued at its present rate the world would, twenty-five years hence, know infinitely more than it knew now.

# THE BACTERIOLOGY OF SCARLET FEVER.

IN the JOURNAL of October 27th (p. 772) some of the recent research work which has been carried out on the bacteriology of scarlet fever was passed in review, and it was noted that a number of different investigators, amongst them Professor G. Caronia and Dr. M. B. Sindoni, have isolated bacteria of the coccal type from the blood and throats of scarlet fever patients, and these organisms, they claim, have a causal relationship to the disease. It does not, however, follow from this that each investigator is dealing with the same type of organism, and Dr. W. Mear has called our attention to the fact that bears a causative relation to scarlet fever is a minute anaerobic diplococcus which grows only on certain media. Professor Caronia informs us that he has cultured the organisms which he believes to be the agents of scarlet

fever and measles on culture media of Dr. Cristina's type (broth-ascitic fluid-human red corpuscles) and of Tarozzi-Noguchi's type. The exact classification of bacteria of the coccal group is a lengthy occupation. To prove that two cultures, apparently of the same species, are identical, necessitates the employment of serological tests and the exchange of cultures between different laboratories. But there are points of dissimilarity which appear in the description of the organisms isolated by some of these investigators which serve to separate them without recourse to this more exacting court of appeal. Thus, whilst Gordon, Bliss, Tunnell, and Dick were working with a haemolytic streptococcus, Caronia and Sindoni were dealing with a small anaerobic diplococcus. A more exact classification of this latter organism is impossible at present, but we were wrong in referring to it as a streptococcus.

The Thomas Vicary Lecture before the Royal College of Surgeons of England will be delivered on Friday, December 7th, at 5 p.m., by Sir Arthur Keith, F.R.S., life and times of William Clift, first conservator. Clift, a Cornish boy, was, in February, 1782, sent with an introduction to John Hunter, who took him as an apprentice without fee on the understanding that he was to write and make drawings, to dissect, and take part in the charge of the museum. Twenty months later Hunter died, but Clift was continued in his employment by Hunter's executors, and in 1800, when the Royal College of Surgeons was incorporated, it appointed Clift to be conservator of the museum. Altogether he was connected with the care of the museum for more than fifty years; he died in 1849.

At the anniversary meeting of the Royal Society on November 30th it will be proposed to re-elect Sir Charles Sherrington, G.B.E., M.D., as president, and Sir David Prain, C.M.G., M.B., as treasurer. Among the members proposed to be elected to the council are Sir Frederick Anderson, M.D., Professor T. R. Elliott, M.D., and Professor D. Noel Paton, M.D. The King has approved the award of a Royal Medal to Professor C. J. Martin, C.M.G., M.B., for his researches on animal metabolism.

We regret to announce the death on November 5th of Dr. T. H. Green, formerly physician to Charing Cross Hospital and author of a textbook of pathology well known to many generations of students. Dr. Green, who was in his 82nd year, was one of the oldest Fellows of the Royal College of Physicians, having been elected in 1875.

After the morning service on Armistice Day (Sunday, November 11th) the Assistant Director Medical Services, London District, and a detachment of the Royal Army Medical Corps will deposit a wreath on the R.A.M.C. war memorial tablet in Westminster Abbey.

At the opening meeting of the University of Paris for the session, on November 22nd, honorary degrees will be conferred on eight distinguished foreign men of science; among them are Professor Golgi of Pavia, Dr. W. W. Keen, formerly professor of surgery in the Jefferson College, Philadelphia, Professor Arturhus of Stockholm, and Sir J. J. Thomson of Cambridge.

At the quarterly meeting of the Medico-Psychological Association of Great Britain and Ireland, to be held at the house of the Medical Society of London on November 22nd, Professor D. C. Winkler will give an address on the psychiatrial and neurological teaching at the Dutch universities, especially at the University of Utrecht, where he is the director of the psychiatrial-neurological clinic.

## Rebueluz.

THE MEDICAL HISTORY OF THE WAR:  
PATHOLOGY.

The latest of the series of volumes of the official medical history of the great war, that dealing with *Pathology*,<sup>1</sup> has a historical as well as a scientific interest. In the later years of the war a most efficient service was evolved whereby physicians and surgeons were able to call in the aid of skilled pathologists and bacteriologists, whether working in the well-established base hospitals or under the more primitive conditions existing at casualty clearing stations or field ambulances. At each halting place of the sick or wounded soldier expert pathological assistance was available, and, though the patient passed on from one unit to another, he carried with him documents recording the investigations carried out in the laboratories of the hospitals through which he had passed, and he often arrived at his destination accompanied by reports describing intricate chemical, histological, and bacteriological examinations performed in the forward units. It is interesting to learn from what humble origin this elaborate organization was evolved. Sir William Leishman tells us in the first chapter of this volume that prior to 1914 no central pathological organization existed in the army, nor had one been contemplated in war establishments. In spite of the comparatively recent experience of the South African war no essential increase or change in the scale of establishment of pathologists had been introduced, and all that was laid down was that each general hospital of 1,040 beds should include in its equipment a well-appointed bacteriological laboratory, and that this should be placed in charge of one or of two officers detailed as bacteriologists. When war broke out the War Office limited itself to the provision of personnel and equipment, leaving it to the medical directorate to employ these to the best advantage. Appointments to the posts of bacteriologists of general hospitals on mobilization were made by the Director-General's staff from such regular specialists as were available, and afterwards from temporarily commissioned officers who had had experience in bacteriology.

The supply of the first group was very soon exhausted: of all the regular officers who had qualified as specialists in bacteriology before the war no more than four remained at this work by the time the campaign was six months old. Practically all the routine pathological work was done therefore by temporarily commissioned officers. The grave problems raised by the unexpected prevalence among the wounded of tetanus, gas gangrene, and the other forms of sepsis led, in October, 1914, to the appointment of Sir William Leishman as adviser to the Director-General of the medical services in all matters relating to pathology and the employment of serums and vaccines. This post he held with great distinction until April, 1918, when he was relieved by Colonel S. L. Cummins.

The need for delegation of part of the duties of supervising and co-ordinating the work of the laboratories became manifest towards the end of the war, and authority was given for the appointment of an assistant adviser in pathology to each army and to each of the principal bases. Under their supervision worked the medical officers in charge of mobile laboratories and the pathologists at base and general hospitals. The dimensions to which the service grew are made apparent by the facts that twenty-five mobile bacteriological laboratories were supplied to armies overseas, and that at the end of 1917 pathologists were attached to 75 of the 85 hospitals serving the British armies in France.

No provision had been contemplated in the war establishments for the installation of central laboratories, to be devoted to research problems, and freed from the burden

of routine duties. Fortunately the elasticity or, as William Leishman puts it, "the fortunate absence of rigidity" of the system allowed the situation to be met in different ways, and at No. 13 General Hospital, Col. Sir Almroth Wright was able to establish by degrees what was essentially a research laboratory, devoted mainly to the study of the pathology and treatment of wounds. Research work in other subjects was organized by the formation of committees of inquiry, who enlisted the services of pathologists specially qualified in the particular lines of research required, and who held meetings from time to time to draw up programmes of research and make the necessary arrangements for their effecting. This brief outline of the organization of the pathological service, drawn from the full and interesting records in the first chapter of this book, illustrates the way in which the scientific side of the medical service developed from very simple beginnings to the complete system which worked so successfully in the later stages of the war.

The remainder, and greater portion of this volume records the advances made in the pathology of wounds and diseases of the war. Sir Almroth Wright's brilliant researches on the mechanism of physiological protection against infection of wounds are concisely described in chapter entitled "The Physiology of Wounds." The experience of the war taught us a great deal about antiseptics, and led to the employment of many new varieties, but experience also demonstrated the limitations of antiseptics, and led many to hold the opinion that the most effective agency to invoke in order to destroy septic microorganisms is the physiological power of the blood. These simple truths might, perhaps, have been stated in simpler language, for most readers will have to consult a glossary of scientific terms in order to understand such a sentence as that which appears on page 57: "The proper conception of drainage is arrived at when it is regarded as a kataphylactic operation whose object is to abolish ecephylactic conditions, and bring the phylactic powers of the blood into action upon the infecting microbes." It is true that these expressions are explained elsewhere in the chapter.

In a chapter on "Tetanus in its Statistical Aspects" it is pointed out that the mortality from this disease fell from 63.5 per cent. for 1914-15 to 37.9 in the 1916-19 period. Statistics of the incubation period show that symptoms manifested themselves in most cases between the sixth and eleventh days, but, on the other hand, there were some which developed as early as the second day after the wound, and others which did not develop until the forty-fifth day. The great importance of the early injection of antitetanic serum is emphasized by both figures and charts. The mortality rate in France in 1916, 1917, and 1918, in protected cases, was 66.5, as against 83.5 unprotected, and in England 22.5 as against 53.3.

Remarkable figures are contained also in the chapter on the enteric fevers. At the beginning of the war soldiers were only inoculated against the typhoid bacillus, but later on a mixed vaccine against both typhoid and paratyphoid fever was introduced with excellent results. A chart of the incidence of these fevers shows that the typhoid rate fell from 80 per 10,000 in December, 1914, to nil, and the paratyphoid from about 38 per 10,000 in January, 1915, to practically nil.

Much was learnt about the pathology of dysentery, both amoebic and bacillary, during the war. In regard to the former type, the new knowledge acquired of the habits of *Entamoeba histolytica* led to relaxation of many of the stern methods of isolation of individuals found to be harbouring this parasite, for it was shown that pathogenic amoebae are often found in the faeces of people who have never left this country, and that in the vast majority of cases infected people merely became healthy carriers of the organism. Obviously, therefore, there is no advantage to be gained by the isolation of carriers of amoebae; they can be set free in a community without grave risk of infecting others. The commoner form of dysentery in the war was the bacillary, and the chapter dealing with this

<sup>1</sup> History of the Great War, Based on Official Documents. Medical Services: Pathology. Edited by Major-General Sir W. G. Macpherson, R.C.M.G., C.B., LL.D., Major-General Sir W. G. Leishman, R.C.M.G., C.B., F.R.S., LL.D., and Colonel S. L. Cummins, C.B., C.M.G., LL.D. London: H.M. Stationery Office, 1923. (Demy 8vo, pp. 600; illustrated. 41 ls. net, post free 41 ls. 9d.)

## THE YOKOHAMA EARTHQUAKE.

## SOME MEDICAL EXPERIENCES.

M. L. YOUNG, M.A., M.B.CANTAB., M.R.C.S. ENG.

It may be of interest to relate some experiences of the recent earthquake in Yokohama, Japan, from a medical point of view. Descriptions of the catastrophe have reached the press over and over again, and it is unnecessary to repeat them. The loss of life has not, and cannot be estimated; the fact that the first shock occurred at a time when cooking was in progress for the midday meal undoubtedly added to the casualties, being responsible for the countless cases of severe burns, so many of which ended fatally, and the typhoon not only caused much death by drowning, but also prevented any attempt to rescue refugees by lifeboats for several hours.

All hospitals in Yokohama fell at the first shock, killing or wounding doctors and nurses, with the result that thousands of victims remained without any medical attention for many hours; indeed many hundreds who might have been saved must have been burned to death by the rapidly spreading fire. This enforced delay added also to the appalling sepsis which confronted us when refugees eventually began to arrive on the ships.

The British ship *Dongola* of the Peninsular and Oriental Steam Navigation Company was at the time lying in Yokohama harbour; she is admirably equipped with medical arrangements, but unfortunately her store of dressings had been depleted after the onward voyage, and this added greatly to the difficulties of handling such large numbers of wounded.

Within a short space of time after the first shock, Yokohama was hidden from our view; dense clouds of smoke from burning wreckage and columns of flame eclipsed everything. The harbour was as usual full of lighters, mostly built of wood, many of which contained Japanese cargo workers, both men and women. These were in extreme danger, owing to the increasing typhoon. Many were completely swamped, with much loss of life, but it was possible to rescue from the water some of those who were comparatively close to the ship; such were our first casualties, remedies, and eventually recovered.

After an enforced delay of some hours, it became possible to lower lifeboats, and rescue parties set out to the shore; they brought refugees of all nationalities in their hundreds back to the ship; the majority were damaged, and many extremely badly hurt. Most of the wounds had no covering, and it was evident that sepsis would be present in an appalling degree. Our first case of extreme urgency was an English boy, aged 11 years, whose right arm was smashed in many places, being merely pulp as far as the insertion of the deltoid muscle. The arm was extremely dirty and the child's general condition was so bad that nothing could be done at the time but to give brandy and morphine and to place the limb in a bath of hydrogen peroxide; some hours later it became imperative to remove the arm; the general condition had improved somewhat, and amputation was performed. Owing to the hopeless conditions, the lack of dressings, and the fact that there was no anaesthetist on board, this took two hours; and some five or six hours later the boy died of shock. In another case, in which the hand only was involved, amputation was performed later with satisfactory results.

Broken bones were numerous, mainly legs and ribs, and unfortunately the fractures were mostly compound and comminuted. A great number of cases of acute conjunctivitis, due to long exposure to smoke, were treated. A great many cases required hypodermic injections of morphine, of which there was luckily a good supply; any form of sterilization of syringes or needles was, however, impossible, owing to lack of time, and yet it is interesting to note that under the very dirty conditions in which drugs were given hypodermically no additional sepsis resulted. The stitching up of countless wounds with dirty catgut and

hurriedly cleaned instruments also had satisfactory results. The stock of ordinary antiseptics was exhausted rapidly, and until help arrived from the French ship *Andre Lebon* no iodine was available, and even the supply obtained from this source was absurdly inadequate. The cutting up of sheets and pillow-cases furnished excellent bandages, but the lack of cotton-wool was serious, and frequently pad splints was impossible. Of stimulants there was no shortage; over forty bottles of brandy and whisky were consumed by the 500 refugees on board within the space of forty-eight hours.

The case of a young Russian child, though deplorable, is of interest; how her injury occurred we could not find out (the problem of trying to understand the many different languages was impossible). She arrived with what appeared clinically to be an appendix abscess developing rapidly into acute general peritonitis; there were no external bruises nor signs of injury; on exploration the abdomen was found to be full of blood, due to a ruptured liver; very little could be done and the child eventually died.

Injuries to joints were common, the most severe being that of a British woman, whose knee-joint was laid open by the falling of part of a building; the wound of course rapidly became infected, and she died on board ship; amputation might conceivably have saved her life, had it been possible to perform it. The Chinese refugees, who on the *Dongola* numbered some hundred and fifty, were in many cases very badly hurt, but none sought help and none uttered so much as a groan; one Chinese woman entered into the first stage of labour while on the voyage from Yokohama, and eventually asked for help. The fortitude and patient suffering of these Chinese men and women were truly extraordinary; one of the women, having a fractured humerus, carried in her arms a baby a few days old only; even in her great anxiety for her child she was patient until the arm could be set.

There were no nurses on the ship, but the British and American women gave of their help so untriggly and worked so well that many lives were saved which otherwise must have been lost. The clothing problem was exceedingly difficult, so many of the refugees being merely in rags. It was possible to supply every refugee in whatever part of the ship with food in plenty owing to the admirable organization of the steward's department.

Our voyage from Yokohama took twenty-four hours, and on arrival in Kobe the Japanese authorities gave every possible aid; excellent arrangements in that place had been made, and we were able to carry out the long task of disembarking the wounded without great difficulty. The more serious cases were conveyed by stretchers across the gangway to ambulances, and on to the International Hospital, where British doctors and sisters in charge of that establishment worked unceasingly to relieve the suffering. The large Oriental Hotel was used as a centre for sorting out the less serious cases, and for relief work, bathrooms and storerooms were rapidly turned into temporary hospitals, and here much valuable medical work was done by Japanese surgeons. British women, themselves refugees in many instances, were everywhere in evidence, giving their voluntary aid unceasingly; many of these women had lost their husbands and children, but I think that the great work they were doing helped for a time to check their tears.

I have said little of matters other than medical. The earthquake itself caused a violent up-and-down movement amongst the crew. Several ships were involved, particularly the *Empress of Australia* and the French ship *Andre Lebon*, both of which had narrow escapes from destruction, being moored alongside the burning wharf. Vertical danger threatened all vessels in the harbour; collision seemed imminent time and again owing to the typhoon and to the fact that visibility was so bad. Lighters and sampans, mostly ablaze, were driven in hope- less confusion amongst the ships by the wind, and the masses of burning oil which poured from the shore upon the surface of the water were a source of intense anxiety. The majority of vessels, however, suffered but little damage, and were finally able to convey thousands of refugees away from the stricken area.

disease will be of great value to those who wish to obtain an outline of the present state of knowledge with regard to the different bacilli capable of causing dysentery, the most reliable methods of laboratory diagnosis, the treatment of dysentery carriers, and the mode of spread of the disease.

We have a discussion occupying twenty-three chapters of the pathology of many different diseases, such as typhus, cerebro-spinal fever, influenza, trench fever, spirochaetal jaundice, acute infective polyneuritis, gingivitis and Vincent's angina, war nephritis and encephalitis. It would occupy too much space to comment on all these, but the interesting and well written chapter on tuberculosis deserves special mention. The tuberculosis mortality rate was higher among men of the Labour Corps of the various countries than those of other units, and the surprising fact may be deduced from the statistics that the incidence of the disease was lower amongst the more urbanized and highest amongst the more isolated and scattered peoples. In the Portuguese troops, coming from a country where industrialism is less developed than in England, both incidence and mortality were much higher than amongst the British. In the Chinese labour units the number both of cases and of deaths was greater than amongst the Portuguese, though less than amongst the East Indians.

The war is blamed for having interfered with many scientific activities, for having discouraged scientists in the prosecution of their researches, and for having retarded the evolution of scientific knowledge. Many of the subsidiary sciences of medicine were not so affected by this gigantic upheaval, but advanced with increased acceleration to assist in solving the urgent problems the war brought in its train. In particular, pathology and bacteriology undoubtedly benefited greatly by the experience of the war, and the practical application of the advances in knowledge made by workers in these kindred sciences played a most honourable part in the successful prosecution of the war, as all readers of this volume of the medical history of the war will agree.

### RADIOLOGY OF THE ABDOMEN IN CHILDREN.

THE third volume of the *Annals of Roentgenology*, entitled *Digestive Disturbances of Infants and Children Roentgenologically Considered*,<sup>2</sup> is the work of Drs. KELLEY and LE WALT in collaboration. The fact that the former is a consulting physician to a hospital for infants, whilst the latter is Professor of Roentgenology at the New York University, adds considerably to the value of the work from the diagnostic standpoint, and ensures a comprehensive view being taken both of the individual diseases and of their x-ray demonstration.

The book commences with a short note on the surgery of infants by Dr. William A. Downes, and following this is divided into two main portions. The first of these, the text, consists of about eighty pages profusely illustrated with photographs of pathological specimens, and, to show technique, with radiographs, and with drawings of operative findings. In this part descriptions of the various diseases illustrated occupy the main portion of the text and references are made throughout to the second part of the book, which is an x-ray atlas. Although dealing entirely with conditions in infants, no attempt has been made to draw too sharp a line, and many radiographs of adults have been used to emphasize some of the points discussed.

There is an interesting chapter on technique which, by means of illustrations, shows the methods of administering opaque food to infants who cannot be persuaded to take food in the normal manner. Then, following a short chapter on the oesophagus, the stomach itself is dealt with fully: congenital pyloric stenosis, pylorospasm, chronic dilatation without spasm or pyloric stenosis, ptosis, and syphilis, are all

discussed. The concluding portion is devoted to the various conditions of the bowel found in infants, including the swallowing of foreign bodies. The chapters on non-rotation of the colon and hernia of the diaphragm are particularly useful.

The atlas contains fifty-four excellent plates which illustrate radiographically all the conditions met with; facing each plate is a description of the case, of the x-ray examination, of the operative findings, and a short comment on the whole. This is printed in English, French, and Spanish, and a liberal use has been made of lettering and arrows to assist study of the radiographs.

This book is one of a series of monograph atlases which is being issued under the editorship of Dr. James T. Case; they are intended to supply a kind of post-graduate course in special subjects, and to form reference books which should be of value to radiologists as well as other medical practitioners. It is a pleasure to handle and read such a book as this; the text is in very legible type, printed on thick glazed paper with good spacing and margins, and the numerous illustrations are of the highest quality and magnificently reproduced; the general arrangements leave nothing to be desired. No radiologist at any rate can afford to be without it.

### THE LIFE-HISTORY OF THE BED-BUG.

IN 1892 the late Mr. Edward Saunders published his *Hemiptera-Heteroptera of the British Islands*, in which he gave keys for the identification of the species of British bugs, and good descriptions of the adults. But he made little or no attempt to deal with the larval stages or the life-histories of these insects. Mr. E. A. BUTLER, in the preface to his new book, *Biology of the British Hemiptera-Heteroptera*,<sup>3</sup> tells us that it is intended to supplement, and not to supplant, that of Saunders. His aim has been "to gather together into one book all the information that has been amassed by various observers, whether in the British Isles, on the Continent, or in America, about the early stages, the life-history and the habitats, habits and distribution of our British species." In all these respects Mr. Butler has succeeded admirably, and British entomologists are under a great debt of gratitude to him for placing at their disposal so much interesting and valuable information about a suborder of insects which has been decidedly neglected hitherto.

About 470 species of heteroptera have been recorded in the British Islands, but, although many of these are of much economic importance, medical interest in this country is confined almost solely to the bed-bug, and other British species of the genus *Cimex*. Of the ova, larval stages, life-cycles, and habits of these, Mr. Butler gives a very full account. Although the bed-bug has not yet been definitely proved to transmit disease to man, it must be regarded as a potential danger, since it is known that various pathogenic bacteria and the protozoan parasite of kala-azar can live in the gut of this insect. Further, the bed-bug demands attention on account of the singular modes of coitus and fertilization which occur in it. It is regrettable that Mr. Butler has only referred so briefly to the work of Berlese, and not at all to that of Major F. W. Cragg on this subject. Even if Berlese's theory of "hypergamies" is untenable, the observed facts as to the fate of the large excess of spermatozoa received by the female bug in successive acts of coitus are of great biological and physiological interest. As Major Cragg's paper (*Ind. Journ. of Med. Research*, vol. viii, 1920-21) is not included in Mr. Butler's bibliography, it is possible that he has overlooked it.

Medical practitioners whose work lies in the tropics will desire to have some acquaintance with other families of bugs than the *Cimicidae*. Several species of *Reduviids* and *Aradids* bite man, and, in the case of the former family, are transmitters of forms of trypanosomiasis. Although, naturally, these exotic forms are not referred to in a book on British Heteroptera, Mr. Butler gives so much informa-

<sup>2</sup> *Digestive Disturbances of Infants and Children Roentgenologically Considered*. By Charles G. Kelley, M.D., and L. T. Le Walt, M.D. New York: Paul B. Hoeber. 1923. (3 x 10 $\frac{1}{2}$ ), pp. xxiii + 81; 54 plates, 156 figures. 12 dollars.)

"I am satisfied that the effective teaching of hygiene in each school and to each class is of the first importance in all grades of schools—elementary, secondary, proprietary and public schools. If for eight or nine years the child is taught of what personal and public health really consists, immense and incalculable good will result. The child and young adolescent have got to be trained in the way of health and physical efficiency. In order to secure this two things are necessary. (i) First, the teacher must be equipped in the subject. He is not born with the knowledge: it has to be acquired. A great responsibility rests upon the teacher, a Training College to provide this preparation for the teacher, some of the Colleges as proved by many of the answers to the examination papers in College and when we as to respect from the candidate is pronounced. College authorities should give by continuing their interest? and arrange for it to be taught by competent persons who understand the whole of question of physical education, including hygiene. (ii) Secondly, the health instruction in the school must be adequate. It should be not only information, but direction: it should be not only in entertainment and theoretical, but continuous and practical. Every young definite guidance should be given and repeated until habits are formed. Hygiene is a habit and a way of life it is of little avail." Until the time given to physical education in the schools is gradually increasing, and special attention is given to it

monary form reported 19,797, and of the number of active children of school-

*Operative Education.*

The principal forms in which education in the open air is practised are: (1) classes in the playgrounds of elementary schools; (2) classes in public parks and open spaces; (3) school journeys to the seaside or country in charge of teachers; (4) holiday or school camps; (5) open-air day rooms; (6) open-air day schools; and (7) residential open-air schools of recovery. The movement has received the active support of the more progressive local education authorities. It is not costly and ought to be more generally employed.

*The Cost of the School Medical Service.*

The items by which the total cost of the School Medical Service is made up include salaries of doctors and nurses, travelling expenses, drugs and apparatus, spectacles, and contributions to hospitals and other institutions. The total was in 1912-13, £828,993; in 1913-14, £355,733; in 1914-15, £411,428; in 1920-21, £1,330,182; and in 1921-22, £1,391,606.

*The Value of Medical Inspection.*

Sir George Newman expresses the opinion that the purpose of the School Medical Service is being fulfilled, though the rate of advance is not so rapid as some may desire, there are no signs of retrogression, and in certain directions the evidence is conclusive of well maintained improvement. In 1920 the percentage of children found defective was 47, and in 1922, 42.2. The subject is discussed in detail under the headings of uncleanness, vision, and tuberculosis. The service "has achieved signal success in its fight with uncleanness of body and head existing among school children." It has to be admitted that sometimes the same children come back numerous times after time, so that correction of home conditions is, as urged by Dr. Barlow (Wallasey), fundamental to permanent success. In London in the earlier years the problem was gross infestation, but efforts "have now resulted in the reduction of the cases of body vermin to the small proportion of two in a thousand of the children examined." In 71.5 per cent. in 1922, and in only 67 per cent. in 1913.

The statistics given show curious variations in the prevalence of defects of vision. Derbyshire had 12 per cent. of defective cases and Hampshire only 4.4, and in County boroughs the range was from 25 per cent. in East Ham to 5.4 per cent. in Hull. The incidence is much heavier in girls than boys. This is ascribed to difference in the occupational pursuits of the sexes in childhood. Spectacles were prescribed in 24,407 cases, and obtained in 21,266. Mr. Bishop Hayman declares that "there is perhaps no range of the surface diseases of the eye," and freedom from the various forms of conjunctivitis and lid infections "may be taken as a barometer of that most distinguishing feature of civilization, personal cleanliness." Rewards of 500 year, principally at school clinics. In many towns squint constitutes a fifth to a quarter of the defects of vision in school children. Mr. Clarendon says that nearly 75 per cent. of cases of squint appear before the end of the fourth year—that is, before school life begins. Usually when first seen by the school doctor vision is defective or lost, so that there should be "the earliest possible detection and treatment." Glasses can be used with negligible risk at a very early age.

Tuberculosis in active and obvious form is not frequent among children of school age. In 1922 the cases of the pulmonary form reported by local education authorities numbered 19,787, and of crippling due to tuberculosis 11,717. The number of active cases is thought to be about 1.5 per 1,000 children of school age. In London arrangements for

is ripe for further

Sir George Newman estimates that 80 to 90 per cent. of children are born healthy, but that 55 to 40 per cent. of those admitted to school at 5 years of age have physical defects which could have been prevented or cured. The problem, he thinks, is ripe for further consideration with respect of "prevention and amelioration consistent with economy and the prevention of waste." Regulations for conducting nursery schools were issued in 1919, but their establishment is retarded by the need for public economy, and only twenty-four (ten of them in London) have been recognized by the Board; but numerous hopeful "experiments" are being made. Day nurseries are valuable for health and hygiene, though they do not commonly include educational provision.

The reports of school medical officers for 1922 show that, despite the need for national economy, much good work is being done. School sanitation is still in many cases defective, and, as pointed out by Dr. Muirholland (Swinton and Pendlebury), the child's training in hygiene is indirectly hindered by the spectacle of school premises with closed windows, defective illumination, lack of fresh air, and obsolete and unclean lavatory and sanitary conveniences. The teaching of hygiene is vigorously discussed in the report, and the concluding paragraph must be quoted in full:

"I am satisfied that the effective teaching of hygiene in each school and to each class is of the first importance in all grades of schools—elementary, secondary, proprietary and public schools. If for eight or nine years the child is taught of that personal and public health necessities, immense and incalculable good will result. The child and young adolescents have got to be trained in the way of health and physical efficiency. In order to secure these two things are necessary. (1) First, the teacher must be equipped in the subject. He is not born with the knowledge: it has to be acquired. A great responsibility rests upon the Training Colleges to provide this preparation for the teacher, some of the Colleges, as is proved by many of the answers to the annual examination papers in hygiene. The ignorance of some of the candidates is profound; that there are to be expected from the children they instruct! College authorities should give this subject careful attention, and arrange for it to be taught by competent persons who understand the whole question of physical education, including hygiene. (2) Secondly, the health instruction should be given and repeated until habits are formed. Good hygiene is a habit and a way of life it is of little avail."

The time given to physical education in the schools is gradually increasing, and special attention is given to it

tion about the families to which they belong that a perusal of his book will be decidedly helpful to workers in the tropics. A list is given of the British Heteroptera, but there are, unfortunately, no keys for their identification. It is true that the author disclaims any intention of supplanting the work of Mr. Saunders, but, considering the high price of Mr. Butler's volume, it seems rather unreasonable to expect the student to purchase another equally expensive and rather scarce volume, in order that he may find out the names of his captures.

Mr. Butler's handsome book is very well printed and produced. It represents an excellent example of the best form of natural history book, written by an accomplished entomologist, who has studied the living insect, and is not merely content to make a collection.

## RECONSTRUCTIVE SURGERY OF THE UPPER LIMB.

DR. STEINDLER's book on *Reconstructive Surgery of the Upper Extremity*<sup>4</sup> is one of a series of surgical monographs published under the editorial supervision of Drs. Lewis, Pool, and Elting. We understand that the five monographs on very diverse subjects are only sold in sets. This rule must surely be discouraging to the surgeon who seeks information on only one of the subjects and does not want the other four books.

In his preface the author says that it is written as a record of personal experience rather than as a textbook. Bearing this in mind, we are prepared to find gaps in the subject-matter of the book where the author's personal experience has not covered the whole of the subject. With these limitations the book may be taken as a valuable and practical guide.

The first chapter is on subacromial bursitis. This disorder does not bulk nearly so largely in orthopaedic literature in England as recently in the United States. The author gives statistics of twenty-one cases of which only eleven were treated, two of them by operation. Five were cured. Fixation in splints or plaster is recommended for acute cases, open operation is regarded as necessary in resistant cases and physiotherapeutics in all. The author's attitude to birth palsy is judicious. The etiology of the condition is various and often obscure. Sever's operation of open tenotomy to correct deformity is said to give better results than operations on the brachial plexus, for which the indications are by no means clear at an early age, when only nerve suture is likely to succeed. Four cases of congenital elevation of the shoulder are recorded. In all the deformity was far more complicated than the title implies, and all were treated by massage and manipulation and gymnastic exercises without operation.

As was to be expected, Dr. Steindler has had considerable experience of the deformities following anterior poliomyelitis. In flail elbow, shoulder, and wrist he has had good results from arthrodesis in the positions of choice. In spastic paralysis Stoffel's operation has given some good results, but arthrodesis of the wrist and plastic operations for flexion contracture of the thumb are preferred. Training, of course, plays a large part in after-treatment. For tuberculosis of the elbow resection in adults and conservative treatment in children gave the best results. The same principles are applied to other joints of this extremity. The chapter on congenital malformations and deformities is full of interest, for the author appears to have had a rich experience, but it is not possible to summarize it in this notice. Traumatic deformities are also well described and discussed and some interesting peculiarities are recorded. There is a useful bibliography to each section of the work and many photographs, some of which, however, are not very instructive, but the diagrams of operative procedures are clear.

<sup>4</sup> *Reconstructive Surgery of the Upper Extremity*. By Arthur Steindler, M.D., F.A.C.S., Professor of Orthopaedic Surgery, Iowa State University Medical School. Surgical Monographs, under the editorial supervision of Dean Lewis, A.B., M.D., Eugene H. Pool, A.B., M.D., and Arthur W. Elting, A.B., M.D. New York and London: D. Appleton and Company. (Sup. roy. 8vo, pp. xix + 310; 50 plates. £6 5s. the set. Issued as sets only.)

## NOTES ON BOOKS.

THE new number of *Brains*<sup>5</sup> contains an account by Dr. Douglas McAlpine of the histological examination, conducted in the pathological laboratory of the National Hospital for the Paralyzed and Epileptic, Queen Square, of two cases of the Parkinsonian syndrome following encephalitis lethargica. The most constant lesions were subacute inflammatory changes and recent perivascular haemorrhages. In one case the substantia nigra showed marked degenerative changes, and the observations are discussed in the light of fourteen such cases reported in the literature. In six cases of encephalitis lethargica calcification in the anterior part of the globus pallidus was found, in one instance as early as the fourth day of the disease. This paper is illustrated by a coloured plate. Another paper in this issue is by Dr. F. M. L. Walshe, neurologist to the medical unit of University College Hospital, who deals with variations in the form of certain reflex movements. Papers on cerebellar localization by Dr. Sven Ingvar of Lund (Sweden), and on lesions of the central nervous system in osteitis deformans by Dr. W. G. Wyllie, and a few notes from recent publications, complete the number.

The thirty-second edition of the Charity Organization Society's *Annual Charities Register and Digest*<sup>6</sup> has appeared. This useful reference book supplies a classified dictionary of charities of all kinds in London or available for the population of London. The charities are divided into those that give relief in affliction (for the blind, deaf and dumb, insane, epileptics, incurables, etc.), relief in sickness (general and special hospitals, medical and surgical homes, and surgical aid societies), relief in distress—(1) permanent (homes for the aged and incapacitated, pensions, homes for youths and children, and educational institutions), and (2) temporary (shelters, and institutions giving relief in money and in kind); reformatory relief (including prisoners' aid societies), miscellaneous charities, including, for instance, training farms for the unemployed, and charities for the protection of the helpless; and, lastly, spiritual institutions. Excluding missionary and religious institutions, which had an income of £3,768,814, the gross income of the institutions enumerated in the *Register* for the year 1921 was £13,654,466. This large sum, however, hardly gives a correct view of the true income of the metropolitan charitable institutions; the voluntary contributions included in this amount to £5,716,943, which sum rather represents income in the sense in which it is colloquially applied. The volume is carefully compiled and well indexed, and gives useful information which cannot easily be found elsewhere.

In view of the opportunity afforded by the war of carrying out on a vast scale both new and old forms of treatment and technique, and in view of the results obtained, Dr. E. M. FOOTE has revised his *Textbook of Minor Surgery*.<sup>7</sup> He has, for example, given accounts of the Carrel-Dakin treatment and of the treatment of burns by paraffin wax, though the author has done well not to introduce hurried chapters on war wounds, as have the authors of many other books. We would have expected more to have been said on the subject of shock, and that the indirect methods of blood transfusion might have been mentioned. The regional method of dealing with the minor ailments of the body naturally leads to a good deal of repetition, and the book will on this account perhaps be of the more service to the casualty officer, the house-surgeon, and the general practitioner, who are concerned with the prompt treatment of such lesions. For the student who is up for examinations the book cannot be so strongly recommended, as the information is too scattered, and he would be better advised to adhere to his own textbooks, in which the classifications are according to systems. In some places the context assumes a certain amount of surgical knowledge—for instance, Nélaton's line is mentioned, although it is not explained, and signs, symptoms, and pathology are not arranged concisely enough to favour ready retention, or in a manner likely to meet the train of thought of the examiner. However, the student might do well to read up the chapter on bandaging, which is better described and illustrated than in most of our own textbooks. It is surprising to find that such old friends as Perthes's, Schlatter's, and Kohler's diseases have not crept into this edition. To those involved in the daily practice of minor surgery this volume still remains a good source of reference and a helpful guide in the matter of practical detail.

<sup>5</sup> Vol. xlv, part iii. London: Macmillan and Co. (6s. net.)

<sup>6</sup> *The Annual Charities Register and Digest*. Thirty-second edition. London: Longmans, Green and Co., and Charity Organization Society. 1923. (Demy 8vo, pp. xx + 533. 7s. 6d. net.)

<sup>7</sup> *A Textbook of Minor Surgery*. By Edward Milton Foote, A.M., M.D. Fifth edition. New York and London: D. Appleton and Co. 1923. (Med. 8vo, pp. xxxi + 245; 440 figures. 35s. net.)

in force for co-operation between the school service and the tuberculous dispensaries. Six local education authorities maintain schools for pulmonary cases, and other 27 residential institutions have been approved by the Ministry. For non-pulmonary cases one authority maintains two schools certified as "special," and 27 institutions are otherwise provided, of which 22 are "approved."

*Secondary Schools.*

The number of such schools inspected in 1922 was 850, and of pupils examined 115,000. The expenditure was £66,000. The work is on the same lines as in elementary schools, and so are the defects found. Deformities are relatively high and suggest that physical training and games are neglected.

*Research Work.*

Sir George Newman urges that there is ample opportunity for field research work by school medical officers and that "no scientific man or woman engaged in the medical examination of thousands of children should be other than an investigator." That important opinion is given, it may be assumed, on the understanding that the school doctor will have time for such investigation, and will not be compelled to pass by with a sigh-matters to which he would gladly devote intensive study if the conditions of his service made it possible. An interesting list of the more important investigations carried out in England during 1922 is given, and two inquiries of special value are reproduced in full. One was the prevalence of deformities resulting from rickets, by Dr. H. P. Newsholme, county medical officer of health for the North Riding of Yorkshire. The other was on a domestic outbreak of gonorrhoea at Hasbourn, by Dr. Allan C. Parsons, medical officer of the Ministry. Both are excellent bits of work. It is also pointed out that intensive medical work in schools revealed to Colonel James and Dr. Parsons that the malaria parasite might be found in English school children and that non-imported ague still lingers in a few districts in this country haunted by the anophelines mosquito.

*THE STATE OF ELEMENTARY SCHOOL CHILDREN.*

Statistics are given showing the number of authorities which have made arrangements for medical treatment, the type of provision, the number and work of school clinics, and the conditions dealt with.

School clinics have been provided by 297 authorities; in London there are 57 clinics (called medical treatment centres) and in addition arrangements have been made with fourteen hospitals. In 1922 arrangements with hospitals were made by 186 authorities, and the number of hospitals undertaking subsidized work was 381. Eye defects, tonsils and adenoids, ringworm, minor ailments, and miscellaneous defects were dealt with.

Treatment of minor ailments was provided by 303 authorities; at Sheffield there were 174,000 attendances and 28,488 examinations. At Liverpool the attendances were close on 200,000. X-ray treatment of ringworm was provided by 145 authorities. In London ringworm cases are becoming less numerous. Middle-class diseases receive much attention, and three forms of treatment are prescribed: (1) the application of antiseptic or drying powders; (2) the coagulation of albumin by zinc ionization; and (3) surgical operation. Of 1,727,314 children medically inspected in London the incidence of such cases is diminishing.

Stammering and other speech defects are treated by only a relatively small number of authorities. Classes have been established in Manchester, Barry, Smeethwick, and London, with very considerable percentages of cure.

*School Nurses.*

The functions of the clinic have developed. It began as a treatment centre, but is now also a health centre and ought likewise to be a research centre. In addition it is now, in well-organized areas, the administrative centre for the service. Still, training, equipment, and buildings should

therefore, it is said, be on a sufficient scale. The school nurses' duty is to aid the school medical officer in his work and to co-ordinate that work with the activities of other departments dealing with public health. Of 317 education authorities, 244 now provide dental work. The school clinics equipped now number over 600, and attendances in England and Wales in 1922 were 4,888,931; about 1½ millions of inspections were made by dentists, over a million cases were referred for treatment, over 570,000 were treated, and 137,000 re-treated. In ten years there has been a great and cumulative improvement. Apart from emergency treatment, school dentists should, it is held, concentrate on children between 6 and 8 years of age.

*Orthopaedics.*

The types of cases dealt with include (a) tuberculosis of bones and joints, (b) paralysis, and (c) congenital or acquired deformities—rickets, talipes, scoliosis, etc. Cripple children constitute 0.5 to 1.0 per cent. of the school population; nearly a third of the cases are due to tuberculosis. About 80 to 90 per cent. of the cripples are curable to the extent of enabling them to take part in industry, if the disability is dealt with early and competently. The provision for treatment includes hospital schools; orthopaedic and after-care clinics; physical defective or cripple schools; remedial exercise clinics, and vocational courses for persons over 16 years of age.

*Defective Children.*

Special schools for defective children are very expensive and the Board urges stringent economy. The number of defectives—blind, deaf and dumb, mental cases, tuberculous cases, cripples, etc.—totalled 152,100 in 1922, of whom 127,600 were found at elementary schools. There is accommodation for fully 40,000 in special schools throughout the country, including over 14,000 in London. There are 32 institutions recognized for training blind and other defectives over 16 years of age.

*The Mentally Abnormal Child.*

Two types of mental abnormality are recognized—the dull and backward, and the feeble-minded. If the best is not made of them the result is apt to be unemployment, delinquency, and crime. In London the number of "backward" school children between ages 8 and 14 is estimated at 10 per cent. If the same percentage applies, the total for the country will be not less than 600,000. The large majority can be taught in ordinary elementary schools, especially in special classes under special teachers. Reference is made to the tests for mentally defective children, and it is noted that "educational" and "intelligence" tests give mutually contradictory results, but Mr. Sherrill states that shyness, obstinacy, or irritability may affect their application. It is believed that 1,000 children in England average attendance there are twelve "educable" mentally defective, or, say, 50,000—certainly not less than 30,000—for England, whereas the special schools have only 16,200 places. Estimates differ as to the percentage that can become fit for remunerative work. The duty of the school medical officer is to classify cases and enable his authority to "clear" them.

*School Meals.*

Power to supply meals was given to local education authorities in 1906, and in 1914 they were authorized to provide them during holidays. The degree to which these powers have been exercised has varied between year and year; the maximum was reached in 1921-22, when 190 authorities fed 592,518 children at a cost of £983,182; of this amount £15,822 was received from parents. The cost for 1922-23 is not known yet, but only 148,536 children were fed, and the total expenditure to be recognized by the Board was limited to £300,000, the responsibility of the guardians of the poor being pointed out, as school meals are not intended to be a form of poor relief. On the question of the nutritional condition of children while wages were high during the war, opinions of medical officers vary, but most of them believe there was improvement. In 1922 health and physique were at least as good as

In *How our Bodies are Made*<sup>8</sup> Dr. R. M. WILSON talks in simple conversational language to very young people; the copious illustrations in the text have some attractive original features; thus an illustration of a healing wound represents the leucocytes as "white submarines mending a cut in the thumb by turning themselves into bricks," and the gastrointestinal tract and its contents are shown as a continuous lake and rivers with tiny ships floating down on the stream. Many medical men will probably think this little volume suitable for their future successors.

The *Pocket Cyclopaedia of Nursing*,<sup>9</sup> edited by Dr. R. J. E. SCOTT, is a useful little reference book for nurses. The subjects with which it deals are arranged in alphabetical order with headings in heavy print at the top of each page in order to simplify reference. This collection of useful information which might be required by a nurse comprises such varied subjects as the technique of an intestinal anastomosis, the removal of stains from linen, Atwater's caloric requirements, the Binet-Simon tests, and the Schick test. The information on each subject is clear and concise, and should prove of great help to the intelligent nurse.

## MEDICINAL AND DIETETIC PREPARATIONS.

### Two New Drugs.

Mr. W. H. MARTINDALE, Ph.D., has recently put on the market two interesting new drugs, aspirodine and sedasprin.

#### Aspirodine.

The formula of aspirodine is  $C_6H_4IO.CH_2CO.COOH$ , and it contains 41.47 per cent. iodine and 53.53 per cent. aspirin. It is an insoluble, practically tasteless white powder which is not affected by weak acids, but which is readily split by weak alkalis into iodine and aspirin. In consequence of these properties it is not dissolved in the stomach and does not produce gastric irritation, but is broken up in the intestine. Iodine appears in the urine within a short time of taking a dose. Aspirodine therefore combines the therapeutic properties of aspirin and iodine in a stable definite chemical compound. The dose is about 5 grains three times a day after food, but this dose may be increased if desired.

#### Sedasprin.

Sedasprin ( $C_6H_4Br.O.CH_2CO.COOH$ ) contains 30.86 per cent. bromine and 69.14 per cent. aspirin. Like aspirodine, it is an insoluble white powder, stable at ordinary temperatures, insoluble in weak acids but rapidly dissolved and split by weak alkalis. The process of its absorption is similar to that of aspirodine. The compound has the combined properties of bromides and aspirin, and therefore should be useful in a wide range of clinical conditions in which it is desired to give a mild sedative and analgesic. The dosage indicated is from 5 to 10 grains three times a day.

Both drugs can be obtained from the firm of W. Martindale, 10, New Cavendish Street, London, W. The price of both is the same, as follows: Tablets (5 grains), 2s. 6d.; 100, 7s. 6d. Cachets (5 grains), 2s. 3d.

## THE SEMON LECTURE.

THE Semon lecture of the University of London was delivered in the Hall of the Royal Society of Medicine on November 1st by Dr. A. LOGAN TURNER, who took as his subject "The advancement of laryngology and otology: a plea for adequate training and closer co-operative action."

After briefly reviewing the position of laryngology in this country in Semon's early days in London in the late seventies, the lecturer proceeded to the main subject of his address, which dealt with a consideration of the teaching of the specialty. The occasion seemed to be very appropriate for its deliberation, as the period was one in which educational changes had been effected and the teaching of laryngology and otology had become a compulsory subject in the medical curriculum. The subject was discussed under three heads: first, the education of the student of

medicine; secondly, the education of the young specialist; and thirdly, the education of the teacher. The three were intimately linked together.

Under the first head, Dr. Logan Turner dwelt upon the advantage to the medical student of obtaining some theoretical and practical knowledge of the commoner diseases of the throat and ear, and the method of dealing with their primary treatment; of recognizing the symptoms which indicated the spread of local infection and the dangers arising therefrom; and the importance of estimating the significance to be attached to symptoms and signs indicative of the existence of systemic disease or a central nerve affection. The preventive treatment of disease in the throat and ear should also be duly emphasized.

The education of the young specialist was a problem of some difficulty, and the question was undoubtedly an economic one for some, and its financial aspects could not be altogether ignored. In every case the course of special training should be preceded by a period devoted to the study of general medicine and surgery obtained by means of a house-physicianship and house-surgery in a general hospital, while some experience in general practice would be of value. The period of special training, which might reasonably cover three years, should include not only clinical experience in a special department, but should comprise laboratory training in pathology and bacteriology; the study of the gross and minute anatomy of the brain in its relation to the specialty, the cranial nerves and their central connexions; the physiology and physics of olfaction, audition, and equilibration; and some knowledge of phonetics. This instruction should be carried out under the control and guidance of qualified teachers in the subjects, who would be prepared to provide the necessary certificates. Clinical experience in an eye department and in the wards of a physician specially conversant with nervous diseases would form a useful part of the training. Six months would be well spent abroad in centres where anatomical material for dissection and operative courses were more easily obtained, and where opportunities for endoscopic work on dogs and the human subject were available. If diplomas were to be conferred, the regulations governing them should exact certificates showing evidence both of clinical and scientific training along these lines. At this point the lecturer dealt with certain suggestions bearing upon the question of diplomas and the Fellowship examinations.

The education of the teacher involved the problem of the better organization and equipment of the ear and throat departments, and increased facilities both for clinical and laboratory research. The lecturer referred to the advantages which the pupil derived from coming in contact with the teacher who was also an investigator educating himself through his own researches. Research work would become facilitated if the work of the staff of the department was co-ordinated and more equally subdivided, so that each member had more time and leisure, and thus retain more energy to pursue the work of investigation. If the junior members were encouraged and properly directed more could be accomplished than had hitherto been done. As the result of such co-ordination it might be possible to establish some co-operative action between the various throat and ear departments in the country, and clinical research along the lines of collective investigation would yield information of real scientific value. A closer working alliance between these departments and other departments of the hospital, and between them and the workers in the laboratories, would lead to the advancement of the specialty in Britain. There were lines of research awaiting co-operation between the laryngologist and the otologist, on the one hand, and the physiologist, the biochemist, and the pathologist, on the other. Veterinary science and the large field of inquiry embraced under the term of comparative anatomy offered great scope for fresh lines of co-operative effort. To maintain an attitude of complacency combined with a sense of complete satisfaction towards things as they exist would inevitably lead to a halt in the onward march of progress. In education there was no finality.

before the war. Sir George Newman thinks this may be due partly to an increased sense of parental responsibility, partly to insurance and union and other payments, and partly to the supervision and assistance of the school medical officers. The £300,000 provided much "supplementary" food, and probably "a substantial amount of the excessive school feeding undertaken in 1921-22 was not necessary to health or life."

**PHYSICAL EXERCISE AND JUVENILE EMPLOYMENT.**

One of the objects of the School Medical Service is to fit the child physically for industry and to prevent premature employment. The Education Act of 1921 forbids the employment of a child under 12 for gain, and limits the employment of children under 14 on school attendance days, besides giving local education authorities power to make by-laws as to mowing and greening and Sunday employment. The Board issued a set of questions to the authorities, and the replies show (1) that certain unsuitable employments—in public houses, slaughterhouses, and barbers' shops—have been stopped; (2) that certain permitted employments are controlled and supervised, and their juvenile workers periodically re-certified; (3) that most authorities require a medical certificate of the suitability of the employment proposed, that many have adopted a system of registration, that many make employers responsible for waterproof garments and footwear; (4) that prompt treatment of defects is secured; and (5) that that partly employed children attend school in a condition enabling them to benefit by the attendance. Much advice is given as to the suitability of proposed whole-time employment, and prospective employers may be advised as to physique, temperament, intelligence, and personality, so that not only shall the worker be fit for the work, but the work shall be the best for the worker.

**WEXMOUTH AND DISTRICT HOSPITAL.**

**OPERATOR OF NEW X-RAY DEPARTMENT.**

The James Miller Memorial Wing, which takes the form of a new and elaborate x-ray department, in memory of the late Dr. James Miller, for many years on the staff of the hospital, was opened on Saturday, November 5th, by Sir Humphry Robertson, K.C.B., who was supported by Dr. A. E. Barclay of Manchester. Apologies were received from Sir Charles Symonds, K.B.E., who was unfortunately indisposed, and others.

Previous to the opening ceremony, about fifty of the leading practitioners of the town, and some of the prominent residents of the town, were entertained to luncheon by the chairman of the hospital, Mr. A. Clarke. The opening ceremony took place at 3 p.m. at the hospital, in the presence of a crowded gathering. Mr. Clarke made a few introductory remarks as to the development which had taken place at the hospital. In introducing the President of the Royal College of Physicians and Dr. Barclay, he said how fortunate the town was in having men so eminent in their profession to address them.

**Sir Humphry Robertson's Address.**

Sir Humphry Robertson began by remarking that at a time when financial stress was forcing many hospitals to close wards the addition of a wing for an expanded x-ray department spoke well for the generosity of the Weymouth public and the energy of that hospital's authorities. This important improvement was appreciably served to the memory of Dr. James Miller, who for fifteen years devotedly served the hospital, and died within its walls on November 5th, 1918, from lung complications of influenza. Like many unselfish men of his profession, he neglected himself in order to care for others, and went about his work with a temperature of 104° F.—a sacrifice which he certainly would not have allowed any one else to make. Always willing to help in any capacity, generous and sympathetic, he was the friend of the poor, but such a life had its only memorial in the gratitude, genuine though necessarily transient, of the poor; fortunately his relations, colleagues, friends, and patients had determined to perpetuate the good work he had so ably carried out by erecting and equipping a new x-ray department. Houtgen of Wurzburg discovered x-rays when working with a Crookes's high vacuum tube electrically excited in November, 1895, and it was there-

the hospital, outlined the progress of x-ray work in the town, and said that from a very small street where he began his work fifteen years ago—when all they had was one small room with a 10-inch coil—they had gradually developed to their present state of efficiency, as evidenced by the fact that exposures which formerly took two minutes could now be done in a fraction of a second. He had no hesitation in saying that the equipment at Weymouth was well up to the standard of any department in the West of England. He said how much the presence of such distinguished men as Sir Humphry Robertson and Dr. A. E. Barclay would help on the work of the department for which he was responsible, and added that he had incurred a debt to Dr. Barclay he could never repay for much valuable help for many years past. He looked upon the magnificent x-ray department at Manchester as his ideal. Dr. A. E. Barclay, of the Royal Infirmary, Manchester, expressed his pleasure in supporting his friend Dr. Rodier Heath's good work, and outlined the progress of x-ray work in Manchester from the time—some fifteen years ago—when the first look charge of the department and they had only one small room and a dark room. At present they had nine sets of apparatus and a large staff of experts. X-ray work required a highly skilled specialist and the work called for a trained eye and brain. During the daily work at the Royal Infirmary, Manchester, there was an interval of half an hour, during which they

of doubtful diagnosis. X-rays were not so widely employed or so well established in treatment as in diagnosis. In some skin diseases and superficial tumours their beneficial influence had been proved beyond question, and the anodyne effect of irradiation had been utilized in uterine fibromyomas, prostatic hypertrophy, erythema, exophthalmic goitre, metrorrhagia, lymphadenomatous and other enlargements of glands, and chronic trachitis, and good results in other affections might confidently be anticipated. But remedies powerful for good were not without risk when employed in large doses, and the dangers attending to x-rays were now fully recognized.

In conclusion, Sir Humphry Robertson said that, important as was a thoroughly complete and up-to-date equipment, the first essential was that there should be a competent radiologist in charge of the department, and the Weymouth and District Hospital was most fortunate in having the services of Dr. Rodier Heath, who for fifteen years had been the pioneer in that town, which thus provided a valuable centre for radiological work.

Dr. P. H. Rodier Heath, the medical officer in charge of the hospital, outlined the progress of x-ray work in the town, and said that from a very small street where he began his work fifteen years ago—when all they had was one small room with a 10-inch coil—they had gradually developed to their present state of efficiency, as evidenced by the fact that exposures which formerly took two minutes could now be done in a fraction of a second. He had no hesitation in saying that the equipment at Weymouth was well up to the standard of any department in the West of England. He said how much the presence of such distinguished men as Sir Humphry Robertson and Dr. A. E. Barclay would help on the work of the department for which he was responsible, and added that he had incurred a debt to Dr. Barclay he could never repay for much valuable help for many years past. He looked upon the magnificent x-ray department at Manchester as his ideal.

has not yet been ascertained. It was first noted in 1897 in New Guinea, but it has been observed also in Siam, Java, Madagascar, in both French and British Guinea, and in Algeria. Drs. Castellani and Tejera describe a skin disease of which we have not previously heard. It occurs in Venezuela, where it is called "cute" and is said to be fairly common. Bright yellow patches with little or no desquamation appear, sometimes in childhood, and very slowly spread. It is thought to be identical with an infection described by Castellani in Ceylon under the name of *tinea flava*. Spores were observed in scrapings from the yellow patches, but no fungus growth could be obtained from them.

At the meeting of the Society for the Study of Inebriety to be held at 11, Chandos Street, W.1, on Tuesday, July 10th, at 4 p.m., Professor A. Louise McLroy will open a discussion on the influence of alcohol and alcoholism upon ante-natal and infant life.

A MEMORIAL to the late Dr. Murdoch Mackenzie was unveiled on June 22nd in the Isle of Lewis Hospital, of which institution he was one of the founders and for twenty-six years its medical superintendent and devoted friend.

THE very fine collection of Hispano-Moresque pottery made by Mr. Francis W. Mark is to be sold at Christie's on July 10th. It contains some rare pharmacy jars of the fifteenth century. Part of the collection was exhibited last summer at the Royal Society of Medicine's social evening.

THE University of London Press announces for early publication an illustrated volume on *The Diseases of the Breast*, by Willmott H. Evans, M.D., F.R.C.S., surgeon to the Royal Free Hospital.

A SECOND (revised and enlarged) edition of Choyce's *System of Surgery*, in three volumes, is announced for early publication by Messrs. Cassell.

## Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology*, *Westrand*, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, *Westrand*, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, *Mediscera*, *Westrand*, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, *Dublin*); telephone, 4737, (Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, *Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

"G. T." inquires if there is any hospital in the British Isles where a native of Sierra Leone, who is an M.A., B.Sc., and M.B., B.S., could obtain a house-surgeon's appointment. Failing such, could the graduate be attached as a pupil to learn the work of house-surgeon and at the same time obtain an insight into hospital administration?

#### UNCERTIFIED MIDWIVES.

"OXON." writes: (1) Is a nurse who holds certificates of proficiency in midwifery, but has not passed the examination of the Central Midwives Board, eligible for registration as a midwife? (2) In the event of her being eligible, am I as a doctor permitted to allow her to conduct cases without my actually being present at the confinement?

"\*." (1) No woman (other than a registered medical practitioner) can act as a midwife in England or Wales unless she holds the Board's certificate. This certificate she can now only obtain by

passing the Board's examination or by being enrolled by virtue of holding the certificate of either the Central Midwives Board for Scotland or the Central Midwives Board for Ireland, obtained as a result of training and examination equivalent to the standard adopted by the Board. (2) If a medical practitioner were to allow an uncertified woman to conduct cases without his actually being present at the confinements, the woman would be liable to be prosecuted and the doctor to be reported to the General Medical Council for "covering" an uncertified woman.

#### INCOME TAX.

"L. B. S." bought a practice as from May 1st, 1921. There appears to be some difficulty in the way of an assessment on the three years' average of his predecessor; "L. B. S." has supplied an account of his cash receipts and expenses to the inspector, who declines to take the receipts on that basis, and claims to add thereto the value of the debts outstanding at the end of the year. He also declines to allow a deduction for removal expenses. The proper basis is of course the average of the three previous years' profits, and if those figures are not available, the profits of the current year are useful only so far as they may serve to indicate what that average probably amounted to, or, if the profits have fallen off, as a basis of adjustment to meet that special case. The inspector's point about the necessity for taking bookings into account during the early years holds good; income tax is payable on profits earned and receivable even though they have not in fact been received. The claim to a deduction for removal expenses cannot be upheld as there is judicial authority against it; the expense is not incurred so much in carrying on the practice as in acquiring it.

"H. E. G." replaced a 10-h.p. S. car by a 10-h.p. F. costing £662/ the cost of a car of similar make and the same horse-power as the S. is estimated at £600. He has claimed to deduct £600—£100 allowed for the old car, net £500. The Inspector of taxes says he is not entitled to replacement cost but to depreciation—for example, £220 (cost of old car), less £100—that is, £120 only.

\*.\* It is beyond dispute that a professional man is entitled to cost of replacement and not to depreciation—which in the long run would be of greater benefit. In the official evidence given before the Royal Commission on the Income Tax it was stated that the cost of replacement would be measured by the expense necessary to replace a machine, and that where that amount exceeded the original cost no restriction would be enforced, except that where the expenditure was incurred partly for improvement the portion so incurred could not be allowed. Assuming that a 10-h.p. car of similar quality and type to the S would cost £600 when the F. was bought, our correspondent is correct in claiming to deduct £500.

### LETTERS, NOTES, ETC.

MESSRS. BOOTS of Nottingham have issued a list of chemicals of guaranteed purity for use in research. The majority of the substances in the list are manufactured by the firm.

#### CORRECTION.

DR. GORDON NORRIE of Copenhagen calls attention to an error in the annotation on the prevention of ophthalmia neonatorum in Denmark published in the JOURNAL of June 23rd. In the fourth line from the end (p. 1062) is a quotation which should read as follows: "it is impossible by prophylaxis to prevent the infection taking place after birth"—that is, in the days after the birth.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 31, 34, and 35 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32 and 33.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 12.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded. Advertisements should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postae restant* letters addressed either in initials or numbers.

were served with coffee, and this half-hour was of the utmost value because during that time they met the members of the surgical and medical staffs and discussed their cases.

Mr. H. H. Du BOULAY, the senior surgeon of the hospital, proposed a vote of thanks to the speakers, and this was seconded by Dr. James Macpherson Lawrie, Deputy Lieutenant of Dorset, to whom the present fine building owes its existence. Lord Ellenborough, chairman of the Dorset County Hospital, also spoke and added his testimony to the great assistance which the x-ray department at Dorchester—also under the charge of Dr. Rodier Heath—had been to the medical and surgical staffs.

#### The New Installation.

At the close of the meeting an inspection was made of the new wing. The main room is a large and lofty one, well lighted by three large windows fitted with wooden roller blinds to exclude the light. Electric fans are used for keeping the atmosphere pure. There is a Snook transformer fitted with auto-control and time switch, capable of an output of 80 milliamperes through the tube; a screening stand, radiographic couch, and various tube stands; and a special couch for use with the Potter-Bucky diaphragm. In another room is a 16-inch coil used for therapeutic work, and great attention has been paid throughout to provide ample protection for the operators. Coolidge tubes are used for treatment and diagnosis and water-cooled and Macalister Wiggin tubes for radiographs. The department also contains the usual dark rooms and office. The apparatus was supplied by Messrs. Newton and Wright and the Cox-Cavendish Electrical Co. The erection and design were carried out by Mr. T. H. Escott, electrical engineer, Weymouth. The Weymouth and District Hospital is a fine modern building, standing in its own extensive grounds, with a private nursing home attached, and is situated just outside the town.

## Paris.

[FROM OUR CORRESPONDENT.]

As the leaves fall so do the doctors return. The medical world of Paris begins to wake up, and the medical societies are announcing their first meetings for the session. It is curious to observe the change the war has worked in the habit of life of the Paris doctor. Nowadays the word "*vacances*"—what you would call the long vacation or the autumn holidays—expresses for us a right if not a duty. Many indeed are the doctors, and among them some of the busiest, who give themselves leave for two good months. Their patients agree that it is necessary, and as a matter of fact all sections of society do very much the same. Then, for goodness' sake, let not our foreign brethren take study leave in Paris in summer; the mot d'ordre there is—go easy.

At that time of year the centre of medical activity is transferred to our thermal stations. There it is intense. Never have our watering places been so thronged, so sought after, as during the summer just passed; all of them are publishing statistics; each one of them is a record.

The causes are manifold. One is that the war sent marching through France millions of men who then learnt to know their own country. Another is that when suddenly our health stations were converted during the war into great centres of hospitalization they had to be thoroughly equipped for the work, and to their previous therapeutic resources was added an arsenal of new methods for physical treatment. In this way they have won quite a new sort of reputation. There has grown up in the public mind a very remarkable belief in what are called natural methods—light, water, air, the simple life—and the belief in chemotherapy has correspondingly declined. Every day some patient will say with a certain naive air of superiority, "I don't take drugs," and this type of patient is predestined to go to a spa, where a scheme of treatment has been systematically planned out and the indications for the use of the waters published far and wide.

International conditions have been especially favourable to France this year. The German spas have not been able during this time of instability to attract visitors, even though the least of them might, when he handled the German currency, fancy himself a millionaire. Moreover, the exchange conditions have brought to France crowds of visitors who in former times would never have dreamt of making the journey, but who nowadays find themselves

able to live luxuriously in the best hotels at prices lower than those of their ordinary life at home. The spas in Czecho-Slovakia have suffered from a cause the converse of this, for in that country exchange rates have considerably improved but there has been no corresponding fall in prices. They have been deserted in favour of greater but poorer rivals. *Beati pauperes*. This unexpected success did not take the French watering places by surprise; their response to the demand on them was limited only by the accommodation available.

Another consequence of the movement which has carried these crowds to thermal stations has been its effect on members of the profession. A well recognized law of political economy is here once more in operation. Some of the most distinguished doctors, certain of a successful career whatever road they took, have chosen that of thermal medicine, which once upon a time was rather despised. The development of hydrology has been quickened by these reinforcements. No longer is it considered sufficient merely to observe patients who present themselves for spa treatment or to build a special clinic. A new spirit of inquiry is evident, and the thermal stations have become centres for research and original investigation. A hospital of a thermal station provides the nucleus round which the laboratories can cluster. There is a rich clinical material in the innumerable patients, constantly replaced by newcomers from all parts of the world. The scaffolding for the study of preventive medicine of the future is being put up in the French watering places, which are serving also as links in the chain of international medicine, so that we can claim that medicine is playing a great part in maintaining the entente, the cordiality of which does not depend on the humour of political virtuosos. The old tradition that medicine knows no frontiers is being revived. It was in England that this sentiment of the international solidarity of medicine first gained strength; it was in the heart of a British member of the profession that the dream of an international society of hydrology was formed; and it was the brain of another which brought the idea to fruition; it was received enthusiastically in France, which was only sorry that it had not originated the idea.

## England and Wales.

### VITAL STATISTICS FOR 1922.

THE Registrar-General's Statistical Review for 1922 is a very "figurative" volume—nearly 500 pages packed full of numerals, not as an appendix to something, but only with a table of contents preceding the figures. The salient features are as follow. The births in the year were 780,124, being 68,690 fewer than in 1921. They yield a birth rate of 20.4 per 1,000 living, this being the lowest rate yet recorded. The deaths were 486,299, being 27,600 more than in 1921, and yielding a rate of 12.8 per 1,000. In 1921 the rate was the lowest on record, 12.1, and 1920 also had a lower rate than 1922, so that 1922 stands only third in order of healthiness as measured in this fashion; nevertheless any of these rates would, if he could come to life again, excite the astonishment and admiration of Dr. William Farr, the first of the Somerset House statisticians, and in this country the father of the modern science. He separated out from the rest of England all the areas which had an exceptionally low mortality, and classed them under the title "healthy districts." And the figure which he chose as the criterion of healthiness was the death rate of 17 per 1,000 per annum. Such places were set on a pedestal for the emulation of the rest of the country. Later there had to be made a new standard, and 15 per 1,000 was adopted. The change is indeed wonderful. As to infant mortality, the total deaths under one year of age were 60,121, equal to a death rate of 77 per 1,000 births. That is the lowest rate ever recorded in this country, and, making every allowance for seasonal influences in respect of summer diarrhoea and epidemicity of children's acute infectious diseases, the 77 rate represents

THE BATTLE  
MEDICAL JOURNAL

Namazi, has recently presented to Shiraz a maternity hospital to provide twelve to fourteen beds, and has promised £100 a month towards its upkeep. Though not a Christian he has placed it under the care of the Church Missionary Society. Medical work was begun by the Church Missionary Society in Shiraz last February, and Dr. Emmeline Stuart, Glasgow medical graduate, who went out at that time, will be in charge of the hospital. The desire of the donor is that the training of midwives should also be undertaken.

The late Mr. Frederick Wolfe, solicitor, of York Gate, Regent's Park, N.W., has by his will bequeathed £2,000 to the Middlesex Hospital, as to one-half for the Endowment Fund and one-half for the Cancer Research Fund; £1,000 each to Charing Cross Hospital for the Endowment Fund and King Edward's Hospital Fund for the Endowment Fund, and £500 each to the Cancer Hospital, Wilham Road, and National Hospital for the Paralysed and Epileptic. He also left £100 to every hospital to which he had been an annual subscriber for at least two years preceding his death. The contingent residue of the estate is to go as to one-third to Charing Cross Hospital for the Endowment Fund, two-thirds to the Middlesex Hospital, one being for the Endowment Fund and the other for the Cancer Research Fund.

According to a report of the State Department of Health of South Carolina, U.S.A., an average of over two persons a day are bitten by rabid dogs in that State, and a campaign is being begun to persuade the State legislature to pass a law to compel owners of dogs to have them vaccinated against rabies. The number of persons bitten by rabid dogs has increased from 176 in 1912 to 769 in 1922, and 3,088 persons have received the Pasteur treatment during that period.

Dr. Jean Paul Langelet, professor of physiology in the University of Paris and editor of the *Revue Générale des Sciences*, died recently at the age of 62.

Letters, Notes, and Answers.

As, owing to printing difficulties, the Journal must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Monday. Original articles and letters forwarded for publication

are unnecessary to be offered to the British Medical Journal. In order to avoid delay, it is particularly requested that all letters on the editorial business of the Journal be addressed to the Editor at the Office of the Journal.

[illegible]

2. FINANCIAL SECRETARY AND BUSINESS MANAGER  
W. STRIND, *London*, telephone, 2630, Gerrard.  
(Advertisements, etc.), *Articulate Westrand, London*; telephone, 2630, Gerrard.  
3. MEDICAL SECRETARY, *Mediscera Westrand, London*; telephone, 2630, Gerrard.  
British Medical Association is 16, South Frederick Street, Dublin (telegams: *Bacilli, Dublin*; telephone, 4737, Dublin) and of the Scottish Office, 6, Rutland Square, Edinburgh (telegams: *Assocate, Edinburgh*; telephone, 4361, Central).

**QUESTIONS AND ANSWERS.**

Dr. GRANT GRAY asks to be told of a good intestinal antiseptic for an obstinate case of mucous colitis. He has tried salol, Lett-naphthol, castor oil (in large and small doses), dimin., charcoal (the most useful), and lavage with quinine solution; but violent attacks of diarrhoea or of an offensive type still persist and debilitate the patient.

TREATMENT OF NEURO-FIBROMATOSIS.

"MR. F.R.C.S." has under his care a girl, aged 19, who is suffering from neuro-fibromatosis. Small tumours began to appear at the age of 7, and at present there are small, soft, fibrous nodules all over the body, arms, and legs, and some on the forearms and neck; the largest is about the size of a pigeon's egg and the nodules are yellowish brown in colour and irregularly shaped. The skin is of a yellowish brown colour and is covered with freckles and small brown spots. The girl is mentally developed, but at times moody and irritable; she does not appreciate her defects, and wishes to go into society.

Among other things the following have been tried; arsenic, dried extracts, highland extracts, excision of the glands (reported to be abnormal), and the use of quinine has been impossible to excise all the nodules, and correspondence with a physician for suggestions as to the treatment for the condition; (2) any sphere of life in which the patient would not be conscious of her defects. It is unnecessary to take expense into consideration.

Dr. A. W. BURTON (South Africa) writes: May I ask for an expression of opinion on the question of the administration of ethyl chloride and chloroform for general anaesthesia? British textbooks make very little reference to such a sequence. An American author (Gwathmey) refers to the special point I should like answered, as: (a) Is such a sequence more dangerous than the adm.istration of chloroform alone on closed inhaler and to follow up with chloroform on an open mask? (b) Is it wise to administer ethyl chloride on an open mask? I noted for many months in the United Kingdom, and must admit that by the same method? I never observed such a sequence used, neither did I ever hear of such ever having been used at any time.

INCOME TAX.  
*Income from Abroad.*

“AUSTRALIAN,” referring to the reply given to “Victorian” in our issue of November 19th, 1921, asks whether income tax is not collected in this country on the whole of the Australian income less the amount of the Australian tax.

\* \* The position is as follows : Income arising from securities, stocks, shares, and rents is chargeable to tax on the full income accrued—less the allowance for Dominion income tax—except where the taxpayer concerned is either not domiciled or not ordinarily resident in the United Kingdom. “Victorian” was in the latter class of persons, and as such was entitled to compute his liability on the basis of the sums received in the United Kingdom.

LETTERS, NOTES, ETC.

CANCER AND CARIOUS TEETH.

BRITISH MEDICAL JOURNAL contains a note on cancer and carious teeth, by Dr. J. L. Love (Simpson, Leeds). During a residence of fourteen years Dr. Love found no cancer among the natives of South Africa, and puts forward the theory that carious teeth are the cause of cancer. In this connection it may be of interest to report that the White Cross located 20 1/2 post-roads. Their teeth had fallen out from scurvy and famine, and among them were found only one case of cancer, and no case of diabetes or appendicitis.

The British Drug Houses, Ltd., have issued a pamphlet entitled *Clinical Pathology and the Use of Stains*, which, in addition to giving a price list of standard microscopic stains, includes some useful practical hints on bacteriological, haematological, and histological methods.

a triumph of well directed infant welfare work. The natural increase of population by excess of births over deaths was 293,895, equivalent to a rate of 7.6 per 1,000 living.

#### THE BANKS MEMORIAL LECTURE.

Sir Arthur Keith, F.R.S., delivered the Banks Memorial Lecture of the University of Liverpool on November 1st. The Vice-Chancellor (Dr. J. G. Adami) presided, and there was a large attendance of medical men and students. In introducing the lecturer, the Vice-Chancellor set forth the circumstances in which the memorial lecture was instituted, and Sir Arthur Keith added some personal traits of Sir William Banks culled from a paper—largely autobiographical in character—which Banks had written. The lecture, an account of which is given elsewhere (p. 888), dealt with the origin and nature of hernial formation. It was illustrated by freehand drawings and its delivery was accentuated by appreciative applause by all present. In the evening the biennial dinner of the Liverpool Medical Institution took place. Dr. J. Hill Abram was in the chair and Sir Arthur Keith was the guest of honour. Its success was largely due to the efforts of Dr. Murray Cairns, who unfortunately was not able to be present.

#### THE LONDON COUNTY COUNCIL'S NEW MENTAL HOSPITAL.

The eleventh mental hospital under the control of the London County Council, which is now approaching completion, is to be known as the "West Park Mental Hospital"; the name originally chosen, and since abandoned, was the "Epsom Common Mental Hospital." Although the hospital is not yet ready for occupation, so many questions in connexion with equipment and administration are arising that it has been deemed advisable to appoint, without delay, the first medical superintendent, who is Dr. Norcliffe Roberts. He has been a deputy medical superintendent in the mental hospitals service, and has acted recently as medical superintendent at the Ministry of Pensions Neurological Hospital, Epsom. The salary is £1,200 a year (based on pre-war economic conditions, with the emolument of an unfurnished house (rates, taxes, and water supply free). The salary is subject to certain temporary additions, in accordance with the cost of living scale, which bring it at the present time to a total of £1,419.

#### HEALTH OF BIRMINGHAM.

The birth rate in Birmingham in 1922, based on a population of 927,844, was 21.5 per 1,000, and the death rate from all causes 12.1 per 1,000. The infant mortality rate was 86 per 1,000 births. The highest birth rate (30.8 per 1,000) was in St. Mary's ward, the highest death rate (16.7 per 1,000) in St. Martin's and Deritend ward, and the highest infant mortality rate (117 per 1,000) in St. Mary's ward. The extension of the city boundaries at the beginning of the present century by the inclusion of a large number of outlying districts has naturally caused a fall in the recorded death rates, which might well be more apparent than real. It is satisfactory to find therefore that in Birmingham as at present constituted the death rate from all causes has fallen from 15 per 1,000 in 1906 to 12.1 in 1922, and that the infant mortality rate has fallen during the same period from 157 per 1,000 births to 86 per 1,000. One of the most pressing needs of Birmingham appears to be an increase in the number of houses for the working classes. Overcrowding, writes Dr. Robertson, is still very acute, and a large number of houses must be erected before the overcrowding is reduced. Some of the overcrowding and discomfort which at present exist is about as bad as it is possible to imagine in a civilized country not in a state of war. Instances are reported in which father, mother, and four or more children have to live and sleep in one room, often an attic, with inadequate cooking accommodation, with no proper food store, no water supply, and no means of getting rid of slops. During the three years 1920-22 the corporation erected 2,279 dwellings, and about a thousand were built by private enterprise, the latter mostly of the small villa type. In ten wards in the city with a total population of over 350,000, not a single house was built during the three years. Dr. Robertson urges the necessity

for proceeding energetically with the erection of dwellings by public enterprise. It is at present useless to expect help from private enterprise, for the reason that the private investor who used to put his capital in this type of investment is now hedged round by so many restrictive conditions contained in recent legislation that an owner of small house property has always been regarded in the eyes of the people as a rapacious individual to the proper care of whose property not the slightest regard need ever be paid.

The prevention of tuberculosis is prominent among the activities of the Birmingham health department. Among the duties of the tuberculosis visitors are those of inducing patients to obtain early treatment, and of inculcating the general principles which tend to prevent the spread of the disease in the home. During 1922 they found among the 2,040 primary cases visited no fewer than 1,054 patients who shared a bed with another member of the family, 269 were sharing a bedroom, and in fifty cases fresh air was not being obtained by means of open windows. In order to remedy the crowding of the healthy with the affected members of a family sets of beds and bedding are supplied to patients through the public health department, sometimes on loan and at other times at cost price or on the hire-purchase system. Among 228 samples taken from milk produced outside the city, 8 proved to contain living tubercle bacilli. Visits by a veterinary inspector to the farms concerned resulted in the slaughter of seven cows giving tubercle-infected milk. The scheme under which the cows of certain dairy farms from which milk is sent to Birmingham are tested periodically with tuberculin was continued during 1922 with respect to 19 herds. The newly tested cows and those tested for the first time numbered 427, and of these 104 failed to pass the test.

## Scotland.

#### CENTENARY OF ROYAL (DICK) VETERINARY COLLEGE.

The Royal Veterinary College at Edinburgh celebrates this month the centenary of its commencement. It began in November, 1823, as the Highland Society's Veterinary School, with a course of lectures by William Dick. In 1916 the College removed to new premises which had been erected near the University, but the funds necessary to complete the new college buildings have not been forthcoming since the war and the centenary is being made the occasion of a special appeal to the public for help. The proceedings will begin on Tuesday, November 27th, with an "at home" in the Veterinary College, when Sir John MacFadyen will present a portrait of William Dick, the founder, to the College, and Dr. Theobald Smith will give an address on comparative pathology. On Wednesday, November 28th, an oration will be delivered by Sir John MacFadyen and afterwards there will be a dinner at the Royal College of Surgeons. From Thursday, November 29th, to Saturday, December 1st, a bazaar is to be held in aid of the College Building Fund; it will be opened on successive days by Earl Haig, the Duchess of Atholl, and Lady Craig.

#### HOUSING IN SCOTLAND.

A statement recently issued by the Scottish Board of Health shows that the houses completed in Scotland in connexion with the State-aided housing schemes down to September 30th, 1923, numbered 22,469 houses, and those under construction 3,143. Under the private subsidiary scheme 2,280 houses had been completed, and in connexion with these the Scottish Board of Health had paid out £545,590 in subsidies. A memorandum issued to the Town Council of Edinburgh states that 1,724 houses have been or are in process of being erected. Of these, 246 are of two rooms, 1,029 of three rooms, 266 of four rooms, and 83 of five rooms. The total expenditure of the Corporation was about £1,250,000, of which about 84 per cent. was borne by the State. There is stated to be an urgent necessity for 1,000 new houses, and unless some new system of building is discovered to meet this emergency the reconstruction of slum property is doomed to further postponement.

The Bradshaw Lecture

NO

MELANOSIS

(MELANOMA: MELANOTIC CANCER).

DELIVERED BEFORE

THE ROYAL COLLEGE OF SURGEONS ON NOVEMBER 8TH,

W. G. SPENCER, O.B.E., M.S., F.R.C.S.,

SCRUINER TO WESTMINSTER HOSPITAL.

(With Special Plate.)

The subject of this lecture, Melanosis, in some of its aspects has engaged the attention of former lecturers and of contributors to the Museum of the College. I propose to relate briefly some recent observations from which there has been obtained an increase of knowledge as well as indications of the lines along which further research is desirable.

Some races of mankind have developed a pigment, melanin, which together with a free secretion from the skin serves to protect the central nervous system against the effects of excess of sunlight, and enables such races to work under the sun in the tropics, because the pigment prevents injury from the ultra-violet light rays. Races inhabiting colder regions, with much less pigment in the skin, have scattered collections of pigmented cells—melanomas. These have the characteristics of "congenital rests," which, although they show no outward change, yet as life goes on undergo an insidious degeneration. Without any sharp line of demarcation the degeneration may pass to the formation of a new growth—melanotic cancer.

Subject to individual differences this malignant change tends to arise in the later periods of life. In horses which turn white with age melanotic cancer supercedes with increasing frequency the longer the animal lives. In man melanotic cancer is a relatively rare form, but it has the peculiarity that two factors are associated—a proliferation of cells and a multiplication of the melanin pigment. The degeneration of the "congenital rest" into melanotic cancer cannot be prevented, nor the further course of the disease controlled. Once the malignant change has started, even although there is no clinical manifestation of it, a metastasis sets in forthwith. The secondary growths, however, displace rather than infiltrate, so that the metastasis may not become apparent for a long while. In addition to those on the surface there are collections of pigmented cells scattered in deeper structures which may be likewise regarded as "congenital rests." Through various causes, moreover, pigmented patches may be acquired which also may tend to undergo malignant degeneration.

Recent chemical observations have overcome to a large extent the difficulties concerning the analysis of melanin. A colourless melanogen by oxidation becomes a coloured melanin and is closely allied in composition to adrenalin. Both are connected with other protein derivatives which have the same feature—that of changing into coloured substances as the result of oxidation. Used as histological stains some of these serve to demonstrate the presence of melanogen in epithelial cells by converting it into melanin. Again, substances contained in coal tar, allied to those derived from proteins, when introduced into animals cause melanin to form, as well as giving rise to cancer. Concerning the history of melanosis I limit myself to noting some of the contributors to the Museum and former lecturers.

Hunter examined the skin of a negro by macerating it, and found that it separated into three layers—cornuous, mucous, and fibrous; the pigment was situated in the mucous layer, which rapidly liquefied and the pigment then collected as a sediment. The skin on the dorsum of the negro's foot was deeply pigmented, that on the sole hardly pigmented at all. The same layer in the skin of a white boy became pigmented after exposure to the sun. Hunter removed a melanotic tumour from below the jaw; such tumours were then included with those styled "fungus hæmorrhoides," as Hunter termed them.

Hunter examined the skin of a negro by macerating it, and found that it separated into three layers—cornuous, mucous, and fibrous; the pigment was situated in the mucous layer, which rapidly liquefied and the pigment then collected as a sediment. In the Museum specimen by Langstaff in 1812. Hunter was the first after Aristotle to advance knowledge concerning the Cephalopoda. The oldest of his specimens, still preserved, is the part of a huge calamary which Banks and Solander picked up off Cape Horn on Cook's first voyage. Hunter's observations included the discovery of the organ for his classical descriptions. In 1818, in his lectures on physiology, and the natural history of man, described the varieties of the coloured races of mankind and aimed to put forward a rational view of the coloration of the negro. The negro was then held to rest under a primordial curse, and the lecturer raised a storm of reproach. Lawrence is now regarded as one of the founders of anthropology, and his lectures as a mine of carefully collected facts. Darwin completed the explanation. He said in his *Descent of Man*: "Hence it occurred to me that negroes and other dark races might have acquired their dark tints by the darker individuals escaping during a long series of generations from the deadly influence of the miasmas of their native countries." Darwin gave to the Museum the painting of the pibald negro boy from South America; Everett Home that of the albino tiger; Jonathan Hutchinson a number of illustrations of leucodermis, vitiligo, and partial albinism. The important *Monograph on Albinism* in Man by Pearson, Nettleship, and Esler, reproduced these and other illustrations in the Museum, and the monograph includes references to much of the subject of this lecture up to 1911.

Following Hunter, the occurrence of melanotic tumours began to be noted by veterinary surgeons; the earliest illustration in the Library, that by Noack in 1820, exhibits a melanotic disease in the anogenital region of a grey mare (Fig. 11). In the same year Fardington published a coloured lithograph representing melanotic growths in man. The classical description of melanotic cancer was given by Paget in his lectures between 1847 and 1852; it was based on specimens still preserved in the Museum and in that of St. Bartholomew's Hospital. The Museum also contains important illustrations by Jonathan Hutchinson besides those already mentioned—for example, drawings of melanotic whitlow, of the unequal distribution of pigment in melanotic growths, and of the senile freckles which may become malignant? Chimney-sweep's cancer attracted the attention of English surgeons from Percival Pott to Billroth, who devoted three lectures to the subject in 1892. Since then there have come researches relating to the influence of gas-tar products, both as regards pigment formation and the production of cancer in mice. Mr. Sampson Handley, in a Hunterian lecture in 1907, described the spread of the melanotic pigment from the new growth to the surrounding tissues, and along lymphatics to lymphatic glands.

The Origin of Melanin Pigmented Cells from

The epidermal origin of the melanin pigment and of the pigmented cells admits of demonstration in several ways, as well as the transference of such cells from the epidermis into the dermis and deeper tissues. On the other hand, that cells definitely mesodermic in origin can form pigment so long as no malignant changes has set in is not demonstrable, the property of the non-carcinogenic mesodermic cell being limited to the taking in of melanin pigment by the cells acting as phagocytes. When melanotic cancer has once started, then the structure of secondary growths resembles sarcoma.

The Formation of Melanin Pigment in the Cytoplasm of the Epithelial Cells lining the Intestine of a Cuttle-fish. The formation of melanin pigment in the cytoplasm of epithelial cells occurs in the Intestine of Sepia, it is a process which was noted in paleozoic times; Belemnites, mesozoic relations of Sepia, had an Intestine measuring up to a foot in length. The remains of the Cephalopoda and of the great lizards which fed upon them are found in strata between the coal measures and the chalk. The Museum specimens were found crushed flat in the Oxford clay at Christian Malford and were described by Owen. His description includes that of the Intestine, the muscular [3281]

## REPORT OF MIDWIVES BOARD FOR SCOTLAND.

The annual report of the Central Midwives Board for Scotland, covering the year to March 31st, 1923, states that the total number of midwives enrolled in Scotland is 5,477, of whom 2,157 have been admitted after examination by the Board, and 3,320 exempted as holding recognized certificates or through having been in bona-fide practice at the passing of the Act. The number of these midwives actually practising at the present time is about 3,000. The names of eight women were removed from the roll during the year. A proposal to increase the period of midwifery training to twelve months in the case of untrained women and to six months for those holding certificates in general nursing has been approved as a general principle, and the Board will make arrangements with the English Board to put it into force if the sanction of the Board of Health to the scheme is obtained.

## Ireland.

## MELANOSIS DERIVED FROM THE EYE.

The first meeting of the Ulster Medical Society for the session was held in the Medical Institute, Belfast, on October 25th. Mr. R. J. Johnstone, M.P., F.R.C.S., introduced the incoming President, Dr. W. St. C. Symmers, Professor of Pathology in Queen's University, Belfast. The new president proposed, and Dr. Calwell seconded, a hearty vote of thanks to Professor Johnstone for his labours for the Society; this was passed by acclamation. Professor Symmers then gave an address. He began by making sympathetic reference to the deaths of members of the Society that had occurred during the past year—Dr. Mary Slade, Dr. Alex. Burns, Dr. W. MacDermott, Dr. H. L. Warwick, and Dr. M. O'Malley. The address consisted of a lucid explanation of a very large number of specimens from three oxen slaughtered in the city abattoirs; they were instances of generalized pigmentation, which Professor Symmers traced from an enormously thickened pigmented layer behind the retina; the optic nerve was deeply stained and a cross-section under the microscope showed a beautiful tessellated appearance, where the pigment had been carried in the lymph stream of the nerve. The brain, the lungs, larynx, and some portions of the liver and kidney were affected; the cartilage of the larynx and bronchi were slightly coloured, as were also lymph glands, the heart, the arachnoid membrane of the brain, and the theca of the cord. He was unable to explain why the pigmented layer behind the retina had become so enormously hypertrophied, but suggested that the pigment, which was very insoluble, had been carried by the lymph stream back by the optic nerve till it finally reached the main lymph channels and so entered the general blood circulation. The lymph spaces in the optic nerve and adjacent parts were crammed full of this pigment, which saturated the pia mater and radiated out into nerves. This form of melanin proved very insoluble and non-irritating. One of the animals was known to be blind. In ochronosis, cartilage was pigmented, but in these cases only the cartilages of the larynx and trachea. Melanotic sarcoma was a dark sepia brown; this was black. He had never seen a similar affection in the human being. Mr. Kirk proposed, and Dr. T. Houston seconded, a very hearty vote of thanks to the President for his address.

## FREE STATE ARMY PENSIONS ACT.

It has been stated that the Army Pensions Act, passed by the Oireachtas, is to come into full force at an early date. An Army Pensions Board has been constituted, and an Army Pensions Office has been opened at 34, Molesworth Street, Dublin, to which all applications will be made for wounded soldiers' pensions, or for allowances and gratuities due to the widows, children, or dependants of National soldiers. The setting of the machinery of the Army Pensions Act in motion will involve the passing of a supplementary estimate by the Dail, and, in all probability, the Minister for Finance will ask for the money at an early date.

Mr. Cecil Lavery, B.L., has been appointed Chairman of the Army Pensions Board. Other members will be: (1) a

representative of the Ministry of Defence, probably General Mulcahy; (2) a representative of the Army Medical Services, almost certainly Major-General Morrin. In addition, there will be members who will interview applicants, etc. Applications must be made through the Ministry of Defence, and the verification of claims will be carried through the Adjutant-General's Office. The scheme of the Pensions Act is comprehensive.

It provides "for the payment of wound pensions to members of Oglagh na hEireann, including the Army and the Irish Volunteers, and also of the Irish Citizen Army of 1916." Thus the Act embraces the whole service period of the Irish Army back to Easter Week, 1916, but pensions can only begin from April 1st, 1922, when the National Army was first with irregulars. Pensions will be paid to non-commissioned officers and men whose degree of disablement is from 20 per cent. to 100 per cent. In the case of officers and men whose degree of disablement amounts to less than 20 per cent., lump-sum gratuities, not exceeding in the case of an officer £100, and in the case of a non-commissioned officer or man £60, may be determined. Wound pensions to officers range from £40 to £200 a year; in the case of non-commissioned officers and men from 8s. 4d. a week to 42s. a week. Additional sums are payable to married officers, and range from 3s. a week to 15s. a week, and to married non-commissioned officers and men additional sums of from 2s. to 10s. a week will be payable. The second schedule of the Act provides for the payment of allowances to the widows and dependants of deceased officers as follows:

Widow—£90 a year during widowhood and £120 gratuity on first remarriage. Each child—£24 a year while mother is living, and £40 if orphaned; 18 is the age limit for boys and 21 for girls. The amount expended on the education of the children between the ages of 12 and 18 will be refunded, but must not exceed the annual sum of £35. Other dependants, to the number of one in each case, will receive £1 a week.

The allowances to the dependants of soldiers are as follows: Widows—17s. 6d. during widowhood, and a gratuity of £45 10s. on first remarriage. Children—5s. a week for first child while mother is living; 8s. 6d. a week for orphaned children, same education facilities as in officers' allowances in certain cases. There also is provided a pension of 15s. a week for a soldier's dependent mother, or for a father who is over 60 years of age, or who is incapacitated by ill health. Only one such allowance, however, is payable.

## Correspondence.

## THE UNIT SYSTEM IN SURGERY.

SIR,—As the head of a "surgical unit" I am interested in Mr. Souttar's letter in your issue of October 27th. I write here of the general desirability or otherwise of the unit system; not of our own recently established unit in the Welsh Medical School, established in a hospital where there was previously no regular clinical teaching, where organization is still in progress, and where there are naturally special problems and difficulties. On the general question I consider it an improvement to appoint in a large teaching hospital someone as organizer of surgical work and director of surgical teaching. This can and should be done without interfering with the position and full liberty of the rest of the surgical staff, to whom the "director" should be really an assistant. I regard the term "unit" as ill chosen; the whole surgical staff should be the unit. The director looks after the surgical side of the hospital. He has assistants, he has an "office." He has his beds and out-patient department. With his colleagues he constitutes a "Board of Surgical Studies," under which he sees to the distribution of work, facilitates the observation of different groups of cases, and organizes teaching and research. Laboratories, library, record office, and workshops are under his supervision. The work of the many surgical special departments is known to him and by him integrated with the general work. There is one harmonious body of men working by diverse methods for the advancement of surgical knowledge. There is no overlapping and full co-ordination.

The director helps in effecting the integration of the earlier with the later (clinical) studies and in maintaining liaison with the medical side. As a professor in the university of which the school is a part, he helps to bring to the school academic advantages. In teaching he knows and watches the career of every student and guides each through his studies.

I visualize such a man as about 45 years of age on appointment. One who has had good experience of hospital work, of pathology, of research, and of specialist surgical practice. I condemn—what may possibly arise in the future—a man

Abres, and a drawing of a Belomonte restored. In one specimen the eight punctate arms are preserved (Fig. 1). The dried black pigment was proved to be identical with the ink of Sepia by Francis Chanvey. After triturating and dissolving it he made a sepia drawing which a distinguished painter pronounced to be tinted with Italian sepia of the best quality.

In Sepia the ink-sac is a diverticulum from the rectum, the fluid being discharged, however, towards the head. There is an orifice, duct, collecting sac or reservoir, and a localized fundus formed by infolding of the sac walls where the ink is secreted. Mr. Burtie has kindly given me stained sections which exhibit the epithelial lining, the cells, and pigment in all stages of formation as follows (Figs. 2 and 3).

(a) Columnar epithelium rests on a basement membrane; the cells have oval nuclei, with one or more nucleoli, many of which are dividing, surrounded by an alveolar arrangement of the cytoplasm. (b) The nuclei are dark dots which tend in the cytoplasm around the nuclei are dark dots which tend to lengthen out into rods, arranged perpendicular to the basement membrane. (c) The superficial ends of the rods have broken off into dark granules or have run together into black droplets, which occupy the superficial portion of the cell. Unpigmented cytoplasm having an alveolar arrangement surrounds the nucleus in the deeper part of the cell. (d) The superficial portion of the cell has become distended with pigment; it disintegrates on the surface like goblet cells of the intestine, and the liberated pigment mixed with mucus collects in the reservoir. The ink fluid is highly diffusible so that it affords the maximum amount of obscuring around the animal. An octopus being repeatedly irritated, at first ejects ink fluid, then fluid less black, until finally the fluid discharged is quite colorless. The fluid has also poisonous properties—a lobster turns on its back, helpless to resist.

### Pigmented Cells Produced in the Epidermis Passing Down into the Dermis and Deeper Tissues.

In embryo frogs branched pigmented cells develop in the epidermis and pass downwards into subepithelial tissues. The ova of frogs are at first unpigmented, then granules of melanin appear in the cytoplasm and serve to protect against the harmful effects of sunlight whilst the ova are floating in the water; for frog embryos at the time of the closure of the neural tube have been killed by exposing them to ultra-violet light rays. Exposure short of a lethal dose causes the rayed epidermis to increase in thickness and multiplies the amount of pigment in the back of a tree-frog embryo exhibits numerous branched cells containing pigment, whilst under the epidermis there are no pigmented cells at all. At the next stage the branched pigmented cells push down processes through the basement membrane into the dermis (Fig. 4). The body of the cell with its nucleus follows, so that there is then a bridge between the epidermis and dermis (Fig. 5). Subsequently pigmented cells are to be seen lying in the dermis with a process stretching up into the epidermis. Finally all the pigmented cells may be found beneath the epidermis (Fig. 6).

**The Formation of Melanin Pigment in the Eye-ball.**  
Melanin pigment begins to appear in the epithelial cells forming the outer layer of the optic cup in the embryo, thick at the forty-second hour of incubation, in the fourth month of the human foetus. Particles of pigment arise within the cells distant from the nuclei; at first gray, the particles become black and rather rod-shaped. The pigmentation begins in the equatorial zone of the future eyeball and spreads forwards more rapidly than backwards. There is formed a single layer of hexagonal pigmented cells, lying external to the rods and cones, with numerous processes into which pigment particles pass as the processes stretch down between the rods and cones. About the eleventh day in the incubated chick, in the seventh month of the human foetus, pigmented cells are found alongside of the blood vessels of the choroid which has developed from the anterior margin of the retinal pigmented mesoblast. The epithelium grows forwards beyond the ora serrata to furnish the pigmented cells of the neural layer of the chorioides and iris. The full pigmentation of the posterior layer of the iris is not complete at birth.

### Scattered Foci of Melanin-pigmented Cells in Deep Tissues.

The pigmented cells of the epidermis and of the eyeball serve a useful purpose; no useful purpose has been assigned to collections of pigmented cells scattered among internal structures. It may be explained that scattered foci of pigmented cells have reached their position during embryonic development. Embryos of fish such as larval eels are at first transparent and pigment can be seen to develop in the eye and epidermis whilst the blood is still colourless. Embryos of bony fish in which the cartilage has been stained to contrast with the melanin pigment serve to demonstrate that pigment cells spread out from around the neural groove and canal in accordance with the segmentation into the metameres (Fig. 7). There is a primitive arrangement of pigmented cells on the surface along dorsal, ventral, and lateral lines and into the rudiments of the fins. Sections through such embryonic fish exhibit deeper collections of pigmented cells, also corresponding to the notametric divisions. Stripes, patches, and markings on the coats of higher animals suggest a connexion with the primitive vertebral segments of the embryo. It seems, therefore, a rational explanation that melanin pigmented cells, whether superficial or deep, have primarily developed around the neural tube, originally for the protection of the central nervous system. The pigmented cells have spread first into the epidermis, then deeper into the mesoblast of the immediate neighbourhood, and further have been carried away in the parietal and visceral layers of mesoderm along with outgrowing nerves, especially sympathetic nerves. Upon this the following classification is based.

**A. Skin.—(1) Epidermis:** Melanin pigment in the cells of the rete Malpighii, to a less extent in those of the rete spinosum, in the corresponding epithelial cells which produce shafts of the hair, also in the dendritic cells of Langerhans lying between the foregoing. The pigmentation of the epidermis varies from a deep black on exposed surfaces of the negro, to be hardly perceptible on most of the skin of blond races when not exposed to sunlight. Yet white races always show considerable pigmentation in the anogenital skin and the arctical of the nipples. (2) Dermis: Pigmented cells with branched processes occur singly, in scattered groups, in patches and streaks. Some lie close under the epidermis, some adjacent to the subcutaneous tissue. They originate as dendritic cells which have penetrated from the epidermis downwards into the dermis, whether already pigmented melanophores, or as colourless melanoblasts which become pigmented in the dermis. The mesoblastic cells of the dermis, as distinguished from cells of epidermal origin, have phagocytic properties and take up pigment freed by the breaking down of epidermal cells. The pigment may be so finely divided as to appear merely a dusky stain, or in the form of granules which pass from the epidermis along lymphatic channels. In lower animals the pigmented cells of the dermis serve a useful purpose in addition to the protection against excess of sunlight—colour is changed voluntarily and reflexly, in mimicry of surroundings; colour serves to differentiate species, and to distinguish sex during the breeding season. The sub-epidermal pigment cells are closely connected with radiating epidermal fibres and nerve fibres, and under the control of the central nervous system, through sympathetic nerve fibres, cause changes in colour; on the one hand pigment granules collect out into the cell processes, the action being similar to that of the cells of the retinal epithelium covering the rods and cones. The differences in colour are partly due to the circulation of blood and to the varying transparency of the overlying skin; hence the change of colour in the dying and dead fish. Whilst the useful purposes served by pigmented cells in the dermis of animals, in human beings the scattered remnants are of no use. Groups of pigmented cells are found deep in the skin, especially of the back in the sacral region. This is the case to a small extent in blond races, but is much more marked among Mongolian, Eastern Asiatic, and Mediterranean races. Infants for some time after birth exhibit bluish, violet, or mulberry-coloured patches, scattered over the sacrum, buttocks, or even the shoulders. There may even be stripes, remnants of vertebral segmentation. The patches are bluish rather than black, although the pigment in the cells is melanin. This is an optical effect of the semi-transparent covering skin, as when tattooing is done with Indian ink. As the skin thickens after birth the patches gradually become invisible, generally before 2 years of age.

taking the post who has had no experience of private practice and whose career has been purely hospital, laboratory, and academic.

With regard to research, some of the director's time can be definitely set aside, granted efficient assistance in other work and when organization is complete. Every new patient and every operation brings opportunities for original research.

Private practice should, in the ordinary sense, not be allowed. In a provincial town at all events the most amicable relations with hospital colleagues are best assured by the professor-director not competing with them. His ordinary working time will be fully occupied and he should be fresh and vigorous for his work, which will not be the case if, for example, an exhausting hospital day is followed by a journey into the country to operate on a suppurating appendix. If the hospital has a private clinic then the director can take his share in its work, including, say, half a day once a week for private consultations at the hospital. Thereby he largely maintains his experience of the whole field of practice, his abilities in all directions are recognized by his students, and there is some addition to his emoluments, all this rendering the appointment more attractive. The pay should be adequate, such as will attract good men from a line of private practice in which the earnings are large. Choice will be limited if only those with a private income apply. The director should be able to maintain as good an external and social position as his hospital colleagues. Incidentally his "budget" should include grants in aid of visits to other clinics.

I am writing of one attached to a hospital of the metropolitan type, but the necessarily utilitarian aspect of such a hospital does not usually provide the best and most diversified material. The ideal is a university hospital which, while fulfilling a public need, is wholly a constituent of the university medical school and is specially organized for research and teaching. I recognize the special difficulties in London, but that they are not insurmountable is shown, for example, by the organization of the surgical unit at University College Hospital.

In conclusion, I refer to certain points in Mr. Souttar's letter. I find it remarkable that at the London Hospital there are "empty beds" which cannot be filled. Here we have a "waiting list" of some 800 surgical patients, and I imagine most hospitals have such lists. A general hospital has to take what comes and special interests of the staff can only be met to a limited extent, although co-ordination and good will among the staff and exciting the interest of outside practitioners can, from time to time, provide groups of cases. Unless he has an exceptionally large number of beds, the director would, I think, have usually to forgo such groups; his beds should illustrate all aspects of surgery, particularly because he is likely to handle students at the beginning of their clinical work, starting them on good general lines. I agree with Mr. Souttar in what he implies that—whatever its defects—the surgical teaching in this country at the present day is at least as good as can be obtained elsewhere. I join him in commending the responsibility under supervision which the student assumes at the beginning and throughout his clinical training. With him I condemn the system which limits the student to the lecture theatre and approve the student's immediate contact with patients in wards, at operations, and elsewhere.

The so-called "unit system" is on its trial, but when it has passed through its period of probation I believe that, under some better name, it will win through.—I am, etc.,

A. W. SHEEN,

Professor of Surgery and Director of  
the Surgical Unit, Welsh National  
School of Medicine; Surgeon, the  
Royal Infirmary, Cardiff.

October 25th.

SIR,—Mr. H. S. Souttar's letter on the unit system at the London Hospital must be extremely interesting to all those who are engaged in the teaching of the senior subjects of medicine. Mr. Souttar alludes to the difficulties with which he has been confronted and suggests that these may be peculiar to the London Hospital or to himself; but it would seem more likely that they are not due to the unit system *per se*, but to the attempt to introduce it into one of the English hospitals, all of which have hitherto been conducted

on very different lines. A new method of teaching or work which differs, or should differ, very considerably from that hitherto in force in English hospitals, is bound to create difficulties.

It is obvious that such a system is workable since the Rotunda Hospital at Dublin has for a long period been in effect an obstetric unit, worked very much on the lines which obtain on the Continent. The fact that the Master of the Rotunda receives his remuneration from the fees of pupils is immaterial; the important difference is that he is allowed to engage in private practice so long as his hospital duties are properly carried out. The duties of the assistant masters and the extern and pathologist are carried out very largely in the manner adopted in Continental units.

Although the system of the Scottish universities—Edinburgh, Glasgow, Aberdeen, and St. Andrews—is not precisely the same, it would seem that the unit system could be established in them with very few minor alterations.

There is no doubt that the head of a unit must always have a considerable amount of routine work to do, but this applies to such subjects as anatomy, physiology, and pathology with almost equal force. In these departments, however, the system has been followed for some years so that it has been possible to adopt the lines of least resistance. There should be little doubt that with a more extended experience in the departments of medicine, surgery, and obstetrics these difficulties would be solved.

As regards private practice, it appears a mistake to debar the head of a unit from consultation work. It has always seemed curious that while the head of a unit is not debarred from any other form of activity in his spare time he is not allowed to undertake consultation work in his own specialty, which is at any rate a means of enlarging his experience.—I am, etc.,

Clifton, Bristol, Oct. 31st.

WALTER C. SWATNE.

#### OPTICAL ESTIMATION OF BLOOD SUGAR.

SIR,—In the BRITISH MEDICAL JOURNAL of October 6th (p. 600) Mr. W. F. Lloyd put forward the suggestion that the refractive index of serums could be used in the estimation of their sugar content.

Having at our disposal a Pulfrich refractometer capable of accurate measurements—the instrument is graduated to read one-tenth of a minute of arc—we have followed up the suggestion, and, as a result of our investigations, consider that a method for the estimation of blood sugar based solely on the variation of the refractive index of serum is impracticable.

In the course of our investigations we made a series of determinations of the refractive index of dilute solutions of sugars. The values obtained are indicated in Table I. The value for the refractive index of cane sugar given in this table is the mean of three readings taken on different days and corrected to 20°C. The temperature coefficient used was 0.00008 per degree Centigrade (the temperature coefficient for water).

TABLE I.

Strength of Sugar Solutions.	REFRACTIVE INDEX.		
	Dextrose.	Cane Sugar.	Cane Sugar (Landholt and Börstein).
1.0 per cent. ...	1.3346	1.3342	1.3344
0.4 " ...	1.3337	1.3330	—
0.3 " ...	1.3333	1.3321	—
0.2 " ...	1.3325	1.3312	—
0.1 " ...	1.3312	1.3309	—
Average variation per 0.1 per cent.	0.00015	0.00015	—

Too much reliance should not be placed on the value of the fifth place of decimals, as the following readings, taken on different occasions, show:

0.1% Sugar ...	1.33304	0.2% Sugar ...	1.33325
	1.33309		1.33319
	1.33314		1.33324
Average ...	1.33309	Average ...	1.33322
Diff. ...	= 0.00005	Diff. ...	= 0.00003

This variation, coupled with the possibilities of slight temperature variations during experiment, renders it impossible to estimate by this method differences of concentration less than 0.05 per cent. dextrose, while it is possible by many chemical methods to estimate variations of 0.01 per cent. or even 0.005 per cent. dextrose.

Another difficulty arises in that the refractive index of human serum is by no means a constant. The following serums—supplied by our bacteriological department—had all been treated identically. In numbers 1 to 4 the Wassermann reaction was negative, in 5 and 6 positive, and in 7 unknown. The proportion of positives and negatives in the pooled serums is unknown.

TABLE II.

	Refractive Index.	Difference from Average.
No. 1 .....	1.35121	+0.00188
No. 2 .....	1.35093	+0.00160
No. 3 .....	1.34875	-0.00058
No. 4 .....	1.34833	-0.00100
No. 5 .....	1.34838	-0.00095
No. 6 .....	1.34875	-0.00058
No. 7 .....	1.34885	-0.00048
(a) Pooled .....	1.34940	+0.00007
(b) Pooled .....	1.34938	+0.00005
Average .....	1.34933	

It will be seen that individual serums differ from the average by amounts far greater than can be accounted for by any conceivable variation of the sugar content.

As blood serum is a complex solution the difference between its refractive index and that of water may be due to many substances. The chief of these are proteins, salts, and sugars. Considering the salt content as equal to a 0.7 per cent. saline and taking cerebro-spinal fluid as roughly representing serum less the proteins it is possible to get an idea of the importance of each factor.

	Refractive Index.
Water ... ..	1.33300
Cerebro-spinal fluid ... ..	1.33475
Serum ... ..	1.34933
0.7 per cent. NaCl ... ..	1.33409
Water ... ..	1.33300
0.7 per cent. NaCl ... ..	0.00109
0.1 per cent. sugar ... ..	0.00015
Other organic substances (urea) ... ..	0.00053
Protein ... ..	0.01456
	1.34933

The alteration in the refractive index of serum produced by diluting the serum with 0.7 per cent. NaCl is shown below:

Percentage of Serum.	Refractive Index.
100 ... ..	1.34940
90 (about) ... ..	1.34763
80 ... ..	1.34596
70 ... ..	1.34446
60 ... ..	1.34331
50 ... ..	1.34194

Average difference per 10 per cent. dilution 0.00149.

It will be seen that the dilution of only 1 in 100 of the serum will give an alteration well within the capacity of the instrument, and that for practical purposes the variation in refractive index may be considered as due to alteration in the protein content.

Further work is being undertaken to determine the importance of "the other organic substances" in causing variations in the refractive index of serum, and also with the view to ascertain the degree of correlation between the protein percentage and the refractive index in normal and pathological serums.—We are, etc.,

Guy's Hospital, S.E., Nov. 2nd.

#### ANTE-PARTUM HAEMORRHAGE AND ECLAMPSIA.

SIR,—No one interested in the etiology of eclampsia can have failed to have read of Dr. Bradshaw's case in your issue of October 20th or Dr. Johnstone's comments in your issue of October 27th (p. 784). Dr. Bradshaw supposes "that the association of placenta praevia and albuminuria is not uncommon"—and perhaps he is right. Whilst from his experience Dr. Bradshaw limits himself to this con-

clusion, Dr. Johnstone proceeds to the justification of the placental hypothesis. The association of albuminuria and accidental haemorrhage, he states, is a commonplace; and the usual interpretation that premature placental separation and haemorrhage result from the toxæmia. This interpretation he discredits; in Edinburgh, he says, several cases have been observed in which the albuminuria has not developed until after the partial separation of the placenta had become manifest. In placenta praevia, presumably, a partial separation of the placenta (with autolysis and bleeding) occurs; and poisons thus arise which, being absorbed by adjacent and still adherent cotyledons, reach the maternal blood and cause the toxæmia ending in eclampsia.

This argument, I submit, is erroneous. The declaration that accidental haemorrhage, at times at least, precedes the "toxæmia," is highly significant. It shows that the distension of the uterus (which occurs when such bleeding is concealed—and when it is not concealed the "toxæmia" is much less likely), and the hardness and tenseness of the abdomen which then result, precedes in time that change in the kidneys of which albuminuria is the mark. It is thus reasonable to conclude that the change in the uterus is the factor affecting the kidneys; but whilst all attention has been directed either to the state of the placenta or to the effect of blood extravasation on the uterine wall, the increase in volume of the uterus in such cases, and the effect this may have on other abdominal organs, has not been looked at. That a very great rise of pressure within the abdomen must occur is obvious; and that this is a factor in the genesis of eclampsia is shown by a consideration of the types of case eclampsia "selects." It is further supported by Dr. Johnstone's statement that "where the haemorrhage is followed by labour within a few hours, albuminuria is not observed . . ." My explanation is that with the emptying of the uterus the pressure falls; but Dr. Johnstone believes that in such case "the toxins have not had time to be formed in the dying portion of the placenta."

But the view that placental necrosis occasions that toxæmia leading to eclampsia, I submit, is untenable. In the first place no toxin (other than normal waste products) in the blood in pre-eclampsia or in eclampsia has ever been found; such has only been imputed. And next, apart from the difficulty of supposing that a particularly inimical poison is generated by dying or dead placental cells, and is absorbed by adjacent living placental cotyledons (in spite of their separation by the decidual processes which extend throughout the thickness of the organ), and so gets into the maternal blood, there is the occurrence of innumerable cases of infarct formation without any preceding sign of toxæmia to explain. There are also the cases of eclampsia cured by treatment with the continuation of the pregnancy to explain—even Dr. Bradshaw's case went on for another month, and was only terminated because of the bleeding. Above all else there is the occurrence of chorion-epithelioma, with metastases (in which many syncytial cells undergo autolysis), without this toxæmia arising.

The occurrence of eclampsia with placenta praevia does not support the view that placental necrosis is a cause or the cause of the pre-eclamptic toxæmia. It is not surprising that a multiparous woman with a placenta praevia should come to pass albumin in her urine; multiparous women are usually older than primigravidae, and their kidneys cannot be expected to be as sound. If the cause which occasions eclampsia occurs in a woman with placenta praevia, albuminuria will arise. Dr. Johnstone, in my opinion, misses the essential point—the type of woman affected with eclampsia. Dr. Bradshaw's patient was 35, and had had two children; whether she was a strong and muscular woman we are not told. Such, we know, if leading active lives (running the house), are very prone to eclampsia. I have previously shown that if eclampsia is not associated with great or rapid distension of the abdomen (and so increased intra-abdominal pressure) it is always associated with a strong muscular state and activity. The same association is found in cattle. In cows a disease essentially similar to eclampsia (so I understand) arises; limited to the parturient act, it occurs always in the best developed

"dopa" reaction does not occur in an atmosphere of nitrogen and is destroyed by heat. The milky juice of plants which yield lacquer is turned black by laccase; tyrosinase is made to change colour up to black by an enzyme, tyrosinase, found in many vegetable and animal materials. A familiar reaction is produced by an enzyme contained in red corpuscles on guaiacum in the presence of oxygen. The blood of some insects turns black on exposure to air from the formation of melanin.<sup>14</sup>

Another set of experiments has the same bearing. Quantities injected pyrolyse, also indole (benzopyrrole) and skatole or methylated indole, under the skin of rabbits, with the result that nine to eighteen days after the injection the skin of the animals became darkened by brownish lines and networks, spots and patches, along with an increased growth of pigmented hair. The pigment was very like melanin; it was not produced by the injection into an albino rabbit, nor in the white areas of animals having the skin partly white, partly coloured. In the albino rabbit the growth of hair was stimulated, but the hair remained unpigmented. Tar painted repeatedly upon the skin of grey or brown mice for several weeks caused a pigmentation of the skin for the formation of melanin in the epidermis. This happens sometimes before the changes set in which lead up to cancer. In white mice, however, whilst precancerous and cancerous changes are produced a preliminary pigmentation of skin does not occur from the rubbing in of the tar. This appears to confirm the absence of melanogen in white mice.<sup>16 17 27</sup>

To demonstrate the presence of melanogen in melanotic cancer D'Agata injected pyrolyse into non-pigmented tumours, rapidly developing secondary to a melanin-pigmented primary tumour in a dog. Pigment was afterwards found but was absent following control injections of safe solutions.<sup>14</sup>

Human melanotic cancer has not been transplanted into mice.

Clinical Observations on the Pathological Formation of Melanin.

The body louse, *Pediculus vestimentis*, when it punctures the skin with its haustellum to suck up blood, at the same time injects fluid from its salivary glands which produces a black spot of melanin pigment in the deepest layer of the epidermis. An emission of the insect's salivary glands has the same effect when injected; fluid from its stomach fails to do so. A man who presented the characteristics of phthiriasis had his back covered by black spots except over a white patch the size of the palm of the hand. This white patch, whether the result of congenital albinism or acquired vitiligo, had remained entirely unpigmented, owing presumably to the absence of melanogen.<sup>18 19</sup>

Women working in ill ventilated coal-tar factories, after inhaling fumes for a time, have exhibited a gradually increasing pigmentation of previously unpigmented skin.<sup>20 21</sup> Arsenic taken by susceptible people to excess produces a pigmentation of the skin along with a keratosis affecting especially the palms of the hands and soles of the feet.<sup>22 23</sup>

In the earlier part of last century, when silver nitrate was administered freely by the mouth, or applied over long periods to the conjunctiva, an intra-vitreal staining by silver nitrate, occurred in some individuals. The face and other parts took on a patchy and diffusely pigmentation of a slaty hue; the conjunctiva became bluish. When fresh skin, or sections of skin cut with a freezing microtome, are treated with a 1 per mille solution of silver nitrate combined with a reducing agent, melanin pigment to darkened it; afterwards there is a reduction to silver oxide. Catechol or pyrocatechin and its derivatives react with silver nitrate in the same way, and this is therefore another bit of evidence as to the composition of melanin.

Variations as to the presence or absence of melanogen in the skin may be held to account for individual differences in the pigmentation of the skin which follow the application of cantharides, the exposure of the skin to sunlight and ultraviolet rays—patches of leucoderma and vitiligo also vary with the actual melanin already present—a

Observations on the Loss of Pigment from the Hair.

Altmann's studies on Old Age assumed that pigment was actually withdrawn from the shafts of the hair, but subsequent observations have demonstrated that coloured, grey, and white hair are produced as such, according as the epithelial cells producing the hair also form melanin or not. Tales of the sudden blanching of hair may be treated with scepticism.

Observations regarding the growth of the summer and winter coat of the variable hare, stoat, etc., show that the change in autumn is due to a growth of non-pigmented hair whilst the brown hair of the summer coat falls out; early in the autumn, on separating the long brown hairs, short young unpigmented hairs are seen to be protruding from the skin. In the spring the variable hare gets rid of its winter coat, not only by licking, but by also "mouthing" the skin.

Observations on the Loss of Pigment from the Hair.

Altmann's studies on Old Age assumed that pigment was actually withdrawn from the shafts of the hair, but subsequent observations have demonstrated that coloured, grey, and white hair are produced as such, according as the epithelial cells producing the hair also form melanin or not. Tales of the sudden blanching of hair may be treated with scepticism.

Tales of the sudden blanching of hair may be treated with scepticism.

Here I just mention the resemblances between the melanin produced in the ink-bag of Sepia and the Tyrian purple of the ancients, which some fishermen still use for marking their linen. Molluscs, Alurex, and Turpura—Alurex brandaris in particular—have a gland connected with the rectum composed of elongated columnar epithelium which secretes a fluid, originally colourless. The fluid under sunlight turns yellow, blue, reddish, violet, and purple. From the glands P. Tridacnoides<sup>24</sup> obtained a dibromindigo in the form of crystals having a coppery hue. Roaf<sup>25</sup> found that fluid from the glands acted like adrenalin in raising blood pressure. In the course of preparation of the dye spoke of this "virus grave in furo," by substances allied to indigo; Piny in describing the garlic-like odour, also a faecal odour such as is produced by the decomposition of the purple was given off a sulphurous preparation of the purple blood pressure. In the course of

Adrenalin and Melanin Derived from a Common Mother Substance.

The note on chemical formulae and various preceding statements lead up to the explanation that the pigmentation which occurs in Addison's disease, also that in dogs after the removal of the adrenals, is due to the accumulation of a mother substance common to adrenalin and melanin. When the adrenals cease to take up this mother substance and convert it into adrenalin, the excess collects in the cells of the epidermis as melanogen to form melanin by oxidation. Pigmentation of a patch of vitiligo was obtained by injecting adrenalin, after which the patch was exposed to ultra-violet light rays.<sup>26</sup>

A solution of melanin was found to have the same effect on the blood vessels of a frog as one of adrenalin, only weaker; on the heart of a rabbit the solution of melanin exceeded in effect that of adrenalin.

Here I just mention the resemblances between the melanin produced in the ink-bag of Sepia and the Tyrian purple of the ancients, which some fishermen still use for marking their linen. Molluscs, Alurex, and Turpura—Alurex brandaris in particular—have a gland connected with the rectum composed of elongated columnar epithelium which secretes a fluid, originally colourless. In the course of

Adrenalin and Melanin Derived from a Common Mother Substance.

animals, in those that have "thrown quickly," in those with the best physique.

The teaching of all this is plain: it is that the toxæmia preceding and causing eclampsia is of mechanical origin—that its rise is to be mechanically explained.—I am, etc.,  
London, W., Oct. 23th. R. H. PARAMORE, F.R.C.S.Eng.

#### THE TREATMENT OF HAEMORRHOIDS BY INTERSTITIAL INJECTIONS.

SIR,—I was very deeply interested in Dr. Dunbar's article on this subject in the *BRITISH MEDICAL JOURNAL* of November 3rd (p. 808), and was gratified to read that he also is practising this method of treatment with such uniform success, because his experience confirms my own, which has extended now over some nine years and which covers about 4,000 cases.

I was sorry to read, however, that Dr. Dunbar employs only a 10 per cent. solution of carbolic acid in liquid extract of hamamelis. Personally, I always use a 20 per cent. solution of carbolic acid in equal parts of glycerin and water, and I have found this to be far more rapid and certain in its effect than the weaker solution which Dr. Dunbar employs. I have treated a patient recently, who had been under the care of another surgeon, who had given him no less than eleven injections of the solution mentioned by Dr. Dunbar. He continued to suffer hæmorrhage from his piles throughout this lengthy treatment, and was still losing blood at every defæcation when he consulted me. This hæmorrhage stopped finally after the very first injection of the 20 per cent. solution, and his hæmorrhoids had entirely disappeared after five injections at intervals of a week. I have frequently tried solutions weaker than 20 per cent. and have invariably found that the effects are less rapid and perfect. It would be a great pity if the progress of the method were retarded by the adoption of too weak a solution.

Dr. Dunbar falls into the common mistake of attributing the success of the treatment to a process of thrombosis. I have pointed out repeatedly (in my recently published book and in previous articles in this and other journals) that injections do not cause thrombosis, but that they act by setting up an aseptic inflammatory process in the submucous coat of the bowel, which compresses the veins and by its ultimate contraction obliterates them and causes adhesion between the coats of the bowel. That thrombosis does not occur, as stated by Dr. Dunbar, is shown, I think, by the almost complete absence of pain in the majority of cases, and by the complete absence of such complications as embolism, pyæphlebitis, and pyæmia, which would be certain to occur occasionally if thrombosis were the usual result of injection. It is just because it is believed by those who have not tried the method that thrombosis is likely to be set up by injection and that embolism and pyæmia are therefore likely to occur in a definite proportion of the cases, that there has been so much reluctance to give the method its proper place as the treatment of choice for hæmorrhoids. If Dr. Dunbar's statement that "The thrombosis produced extends along the veins until they perforate the coats of the rectum" is left uncorrected, it will have the effect, I fear, of making his readers extremely nervous of recommending patients to undergo treatment by injection. If thrombosis were really the result of injection of carbolic acid into hæmorrhoids, it would be difficult to see why more than one injection should be required. Amongst the 4,000 cases which I have treated by this method, I have only had one definite instance of thrombosis.

I join issue with Dr. Dunbar also when he states that not more than three piles should be treated on any one occasion. I have repeatedly treated as many as six piles at one sitting and have used as much as 40 minims of 20 per cent. carbolic acid, but I have not yet met with a case of carbæmælia as a result.

If Dr. Dunbar will try the solution I recommend, I venture to predict that his results will be even better than those he records in his very interesting paper, and that he will find that even in the worst cases the symptoms of prolapse and hæmorrhage will cease from the moment of

the first injection and that his patients will need only from three to six injections at weekly intervals, instead of an average of nine or ten injections usually recommended by those who use the solution Dr. Dunbar employs.

I, like Dr. Dunbar, have tried other solutions, such as that of the hydrochloride of quinine and urea, but I have always returned to the 20 per cent. carbolic acid in glycerin and water, because I find my results are incomparably better with that than with any other.—I am, etc.,  
London, W.C., Nov. 3rd. ARTHUR S. MORLEY, F.R.C.S.

#### THE USE AND ABUSE OF OBSTETRIC FORCEPS.

SIR,—With your permission I would like to refer to the discussion on the use and abuse of forceps by the Section of Obstetrics and Gynaecology, reported in the *JOURNAL* of October 6th.

During the meeting it was manifest that there were two sides debating. The actual point of divergence of opinion, though amply illustrated, was never, I believe, put into words. This crux was "maternal distress," and I submit that it is the estimation of this factor by each individual practitioner that finally governs the use of forceps in general. Instances of gross abuse of this indispensable instrument, such as Mr. Comyns Berkeley quoted, came as a shock to many of his audience, and it is greatly to be hoped that they are rare.

As to the incidence of prolapse, this unfortunate condition undoubtedly follows spontaneous as well as assisted labour. May it not be more the result of labour prolonged beyond the point of ready recuperation in the individual circumstances of each patient? If so, the earlier application of forceps at times actually may be a prophylactic measure; further, the blame attached to the instrument in a proportion of cases may really be due to the delay in its use.

May I also remark that certain figures which I quoted for Caesarean section only applied to those in which all hope that the uterus was still uninfected had been lost before operation?—I am, etc.,

R. KELSON FORD, M.B., B.S.

Municipal Maternity Hospital, Southsea, Nov. 5th.

#### LARGE PLEURAL EFFUSION.

SIR,—The cases of large pleural effusions described in the issues of the *JOURNAL* of October 20th and 27th induce me to send some notes of one of mine, which I think may prove to be interesting.

In May, 1910, I was asked to see a young man who had left hospital a week before, and who was supposed to be dying. His relatives stated that they had been told that he was suffering from an inoperable solid tumour of his lung. The left chest was dull all over, heart displaced to the right, the glands in the anterior and posterior cervical triangles, axillæ, and groins were enlarged, and the skin bronzed. The temperature was normal, but he said that he was subject to "attacks of shivering." He denied having had syphilis, and there was no history of lymphadenoma or tuberculosis in his family. The sputum never contained tubercle bacilli.

A hypodermic needle proved that there was fluid in the left pleural cavity, and with a Dieulafoy's aspirator I removed enough to fill an ordinary wash-hand basin to an unsafe level, and partially fill another. The amount unfortunately was not measured, but must have been at least twelve pints. Three days later I aspirated ten and a half pints, and twice each week, during the succeeding two months, eight to nine pints were withdrawn at each paracentesis.

In the third month the chest refilled so rapidly that it was necessary to increase the number of tapings to three, and then four weekly, and this continued, until at the end of the fifth month he died of coma.

After the first few tapings the patient, far from experiencing discomfort or fear, expressed a wish for a daily paracentesis, watched with interest all that took place, would assist if permitted, and looked forward to twenty-four hours of relief, and even enjoyment.

He was tapped forty-seven times, which is unique for Hodgkin's disease, tubercle, or any other disease as far as I can learn, and the total amount of fluid removed should constitute a record.—I am, etc.,

Bournemouth, Oct. 23th.

Fig. 6—Tree-frog embryo: skin, subcutaneous tissue, muscle. All melanophores in subcutaneous tissue. (Kornfeld.)

Fig. 7—Embryonic bony fish—cartilage stained; melanophores lateral lines. B, Alburnus; C, Alburnus—older; D, Alburnus; E, Alburnus; F, Alburnus; G, Alburnus; H, Alburnus. *Alburnus lucidus*: melanophores in each segment. H, fork boops—2 cm. in length; golden stripes when full-grown. (Bolk.)

SIR,—I would also like to record a case of large pleural effusion which came under my notice in August, 1918, whilst doing temporary duty at a prisoners of war hospital at Manchester. A German, who no doubt had been rather overlooked owing to the rush of surgical work, had been in the medical ward some weeks, and was reported by the sister as "not much wrong with him." He was getting up every day, and acting as orderly and generally assisting with cleaning, etc., in the ward. I was almost passing him over as he had been passed over before, for he did not look very ill and hardly complained of any symptoms. But on questioning him he said he felt a very slight pain on the left side of his chest and was rather short of breath on exertion. When he had undressed I immediately noticed obvious bulging on the left side. I aspirated the chest with a Potain's aspirator and withdrew a gallon less three ounces of serous fluid. He felt quite fit and much relieved at the end of the operation and was doing well four days afterwards. After that time I was unable to follow the case, as I was ordered to France again.—I am, etc.,

ALLAN DEWAR,  
Captain, late R.A.M.C.

Tuxford, Notts, Nov. 3rd.

### CHRONIC INTESTINAL STASIS AND CANCER.

SIR,—Sir Arbuthnot Lane in his address on chronic intestinal stasis and cancer published in the *BRITISH MEDICAL JOURNAL* of October 27th, and in a previous letter to the *Times*, seems to imply that cancer has no other cause than chronic intestinal stasis and that all efforts to discover the origin of cancer which are not based upon this view are more waste of time and money.

That cancer requires a suitable soil for its development is now perhaps generally admitted, but that that soil is provided solely by the action of intestinal toxins is open to question. How, one may ask, do the toxins of intestinal stasis affect the incidence of cancer upon the scar of an old x-ray burn, upon an old scar of lupus, or upon an old syphilitic scar? What have intestinal toxins to do with the pre-cancerous conditions of the skin due to arsenical dermatitis or to the prolonged contact with tar?

It might indeed be argued that these pre-cancerous conditions of the skin, induced by various agents, render the affected part more susceptible to those intestinal toxins which prepare the way for cancer. In that case, those whose skins have unfortunately been burnt by x rays or damaged by chronic arsenical poisoning should be able to avoid the subsequent development of cancer by adopting a primitive diet and by swallowing liquid paraffin!

But how can one explain the occurrence of kangri cancer of the abdominal walls in natives of Kashmir, among whom the incidence of cancer is above that of other native races, not as the result of a civilized diet, but because they have the habit of wearing next the skin of the abdomen kangri, or vessels containing live charcoal, which by constant burning of the skin produces a pre-cancerous dermatitis?

Without denying the influence of intestinal stasis in producing cancer of the digestive tract, is it not just as reasonable to suppose that cancer in these parts may be secondary to damage resulting from local inflammatory conditions brought about by stasis, as it is to affirm that degenerative changes due to hypothetical toxins prepare the way for cancer not only in the digestive tract but in all other parts of the body also?—I am, etc.,

London, W., Nov. 6th.

H. G. ADAMSON.

### MENSTRUAL DISABILITY.

SIR,—I notice in the *JOURNAL* for October 13th a letter from Lady Barrett, in which she states: "Now happily the more rational life lived by women to-day has so altered the incidence of pain and malaise during menstruation that, whatever may have been the fact in the past, recent investigation shows that a very small minority of women suffer from any such disability."

My own experience has been the very opposite to this. Since the war I have been very much impressed by the number of girls who are brought to me suffering from great disability during menstruation. Not only that, but

the mothers have asked me why so many girls do suffer so much now; because when they were young they hardly ever heard of such a thing.—I am, etc.,

Uttoxeter, Oct. 20th.

H. FOXTON.

### LATE RESULTS OF OPERATION FOR CANCER OF THE BREAST.

SIR,—The Medical Society of London has appointed a committee of surgeons to investigate the later results of operations for cancer of the breast. The scope of the inquiry at present is being limited to cases of patients who are known to be alive not less than ten years after the primary operation for undoubted cancer.

A preliminary inquiry has already brought to light the existence of a number of such cases, and the Society is therefore encouraged to make a wider appeal.

The committee would be obliged if any medical practitioner, who has not already been approached, having personal knowledge of any such cases, would communicate with the Honorary Secretaries of the Society.—We are, etc.,

T. P. LEGG,  
F. LANGMEAD,  
Honorary Secretaries.

11, Chandos Street, Cavendish  
Square, W., Oct. 27th.

### Obituary.

#### PETER WALLWORK LATHAM, M.A., M.D., F.R.C.P.,

Consulting Physician, Addenbrooke's Hospital, Cambridge;  
formerly Downing Professor of Medicine.

MANY among the generations of Cambridge medical men during the last sixty years ending 1912 will be reminded by the announcement of Dr. P. W. Latham's death of a once familiar figure in the streets of their Alma Mater, and will feel that a link with the past has gone. For the last ten years he had lived in retirement in London, but still maintained relations with old friends and attended meetings of a social medical club within the last year.

He was born on October 21st, 1832, at Wigan, the eldest son of John Latham, a medical man in that town, but was not related to the famous physicians John and Peter Mero Latham. After serving as apprentice to his father, he continued his medical education at Glasgow, and in 1854 went up to Caius College, Cambridge, where he obtained a scholarship in the following year; in 1858 he was 19th Wrangler in the mathematical tripos, and in 1859 was placed first in the first class of the natural sciences tripos with distinction in no less than five subjects—chemistry, physiology, physics, comparative anatomy, and botany—a record that has never been equalled. He then worked at St. Bartholomew's Hospital, and in a very short time, in 1860, was elected a fellow of Downing College, Cambridge; in the following year he proceeded to the degrees of M.A. and M.B., became a member of the Royal College of Physicians of London, and in April, 1862, was elected assistant physician to the Westminster Hospital.

His professional life in London, however, was short, for in 1863 he returned to Cambridge as physician to Addenbrooke's Hospital and medical lecturer at Downing College. The subject of pulmonary tuberculosis then attracted his attention, and in 1864 he read his M.D. thesis "On the early symptoms of phthisis and the means best adopted to prevent or arrest its development," but unlike his son, who also took up this study at about the same time in his career, he did not make it his life's study. *Nervous or Sick Headache* was the title of a small book, published in 1873, containing two lectures given at Addenbrooke's Hospital, in which he urged the importance of bracing up the bodily and nervous systems in the intervals between the attacks by strychnine, iron, and cod-liver oil. *Quain's Dictionary of Medicine* also contained an article by him on this subject. From 1868 to 1874, when he was elected Downing professor of medicine, he acted as deputy for his predecessor Professor W. W. Fisher, who had held the chair since 1841. Probably realizing that a lengthy tenure of office may have its drawbacks for the University, Latham resigned the chair after twenty years' service in 1894; during this period he played an active part in the medical school of the University

W. G. SPENGLER: MELANIN: MELANOMA: MELANOTIC CANCER.

Fig. 16.—Melanotic cancer spreading from pia mater into brain. (W. G. S.)

then reaching its high success under the leadership of Sir George Humphry and Sir Michael Foster, with whom, however, he did not always see eye to eye. In 1899, at the age of 67, he voluntarily resigned his post as physician to Addenbrooke's Hospital after thirty-six years' service, remaining in Cambridge until 1912, when he settled down in London. In May of this year he moved to 15, Royal York Crescent, Clifton, Bristol, where he died on October 29th, just a week after his ninety-first birthday.

At the Royal College of Physicians, of which he became a Fellow in 1866, and at the time of his death was the Senior Fellow on the list, Latham played an unusually prominent part for a country Fellow, being senior censor (1894) as well as censor (1887-8) and councillor (1886). His Croonian lecture for 1886 "On some points in the pathology of rheumatism, gout, and diabetes" contained a number of formidable-looking chemical formulae, and gave the results of his work on the formation of uric acid previously published in 1884. Two years later he delivered the Harveian Oration dealing with micro-organisms and blood infection. At various times he wrote, as a general physician should, on various aspects of medicine, such as the *Pathology and Treatment of Typhoid Fever* (1895) and on *Rheumatoid Arthritis* (1905), in which he advocated continuous counter-irritation of the spine by blisters applied in the neighbourhood of the cervical and lumbar regions.

In his prime Latham was a handsome and striking personality with a pleasant and genial manner, and was fond of social intercourse. As a careful and sound physician he for many years deservedly enjoyed a large practice in and about Cambridge. His independent mind made him a keen fighter, and he sometimes expressed his views with such conviction that the opposition remained unconverted, if not confirmed in their opinions. But these are matters of long ago and they are mentioned only to show the vigorous mentality of the veteran physician who in his day was a notable character in Cambridge.

#### H. R.

The funeral took place on November 1st at Canford Cemetery, near Bristol; it was attended only by relatives and intimate friends; the service was conducted by Bishop Clifford.

#### PERCY WHITTINGTON SAUNDERS, M.B. TORONTO, F.R.C.P. LOND.,

Physician to the Royal Free Hospital.

WITHIN three days the Royal College of Physicians has lost its oldest and also one of its junior Fellows. On October 29th Dr. P. W. Latham died full of years and honours. On November 1st Dr. Percy Saunders passed away at the age of 46, just as the strenuous toil of years was reaching fruition. Born and educated in Canada, he gained the degree of M.B. (with gold medal) at the University of Toronto in 1902. Having decided to try his fortune in London, he came to this country and took the M.R.C.P. After holding a succession of posts at the City of London Hospital for Diseases of the Chest, he became connected with the National Hospital for the Paralysed and Epileptic, Queen Square, where he was in turn house-physician, pathologist, registrar, and assistant physician. In 1913 he was appointed assistant physician to the Royal Free Hospital. He contributed a number of articles on neurological subjects to medical literature. During the last five years his health suffered severely from several attacks of influenza, but he finally succumbed, after a long illness, to an obscure form of malignant disease.

Such are the bare facts of his professional career, but they entirely fail to convey any adequate idea of the enormous amount of work Saunders accomplished during the twenty years he spent in London. How well that work was done is sufficiently shown by the way in which he was promoted from post to post at the hospitals with which he was associated, and by the high professional position he attained after coming to this country as a total stranger, to make his way solely by his own merits, without any influence whatsoever. In everything he undertook he gave of his best, working incessantly to the utmost limits, and frequently beyond the limits, of his none too vigorous physical powers. Often, after a long afternoon spent in

seeing out-patients and teaching students at the Royal Free Hospital, he would proceed to "The National" to do some work as registrar, would then give a lecture to nurses, and finish up by reading and writing well into the early hours of the morning. Absolutely conscientious in everything he undertook, his colleagues knew that anything he promised to do would be done thoroughly and well to the smallest detail, no matter at what expenditure of time and trouble. In disposition he was singularly shy and retiring, entirely lacking in the arts of self-advertisement and pushfulness. It was no easy matter to penetrate his natural reserve, but once known he was the most faithful of friends, only too ready to sacrifice his own interests on behalf of others, and seemingly incapable of an unkind or ungenerous word or action. His death is a grievous loss to the hospitals he served so faithfully. His sun has gone down while it was yet day, but the influence of his example and of his character will live. Those who knew him best, when they think of the apparent tragedy of his premature death, will recall the lines of Tennyson on another such loss:

And, doubtless, unto thee is given  
A life that bears immortal fruit  
In those great offices that suit  
The full grown energies of heaven.

#### WILLIAM HALL, M.R.C.S., Leeds.

WE regret to record the death of Dr. William Hall, at Headingley, Leeds, on October 31st, in his 80th year. Dr. Hall was the son of a well known Leeds medical practitioner, Mr. Matthew Hall of Wortley, and was born in 1834. When his father died, at the early age of 40, William Hall, although only in his 15th year, was apprenticed to Dr. Radcliffe of Leeds, and in the cholera and typhus epidemics of 1848 and 1849 worked night and day among the poor inhabitants of Leeds. In 1850 he became a surgical dresser to Mr. Sam Smith, surgeon to Leeds Infirmary, and two years later he was dresser to Mr. Teale. He obtained the diploma of M.R.C.S. Eng. and the L.S.A. in 1855, at the age of 21; subsequently he was a clinical assistant to Sir William Gull at Guy's Hospital, and also worked at the Lariboisière Hospital, Paris. He went into practice in Leeds, and became honorary surgeon to the Leeds Women and Children's Hospital and lecturer on midwifery and diseases of women and children at the Leeds School of Medicine; he also held the appointment of factory surgeon for seventeen years. It may be noted that Sir Arthur Mayo-Robson began his distinguished career in Leeds as Dr. Hall's junior partner.

Dr. Hall had a serious illness in 1897, and soon after retired from practice. Not for long, however, was he content with a life of leisure, and on recovering his health he devoted his energies to improving the conditions of the poor children of Leeds. He was one of the pioneers of the child welfare movement and began on an experimental scale the system of providing free meals daily to poor school children. Within a few months he examined 1,600 board school children in Leeds, and found that 600 of them suffered from rickets and had bad teeth; he soon had convincing proof of the efficacy of supplying those children with free meals. The Bradford City Council, as a result of Dr. Hall's experimental work, set a precedent by deciding that poor school children should be fed out of the rates, and Dr. Hall lived to see his pioneer work completed by the passing of an Act of Parliament empowering educational authorities to feed necessitous school children. He also founded the Leeds Barefoot Mission in 1904, which provided clogs and clothing for the children of the poor.

Dr. Hall married Miss Bowe, of Richmond, Yorkshire, who predeceased him, and he is survived by two sons and one daughter. The elder son is Dr. R. H. Hall of Leeds, who succeeded to his father's practice, and the younger son is Mr. Basil Hall of Bradford, president-elect of the British Medical Association.

We are indebted to Sir Clifford Allbutt for the following tribute to Dr. Hall's memory:

When in the early sixties of last century I settled in Leeds Mr. William Hall was gathering around him a substantial junior family practice; while I was living chiefly on

FIG. 1.—Multiple closed fractures of all four limbs, sustained in a fall from a height of 20 feet. After treatment, the patient was allowed to get up and walk, and was discharged from the hospital, and sustained no further complete fractures.

FIG. 2.—Showing the method of plaster applying of any fracture of the lower limb—in this case one of the middle third of the femur—with a window cut in the clothing.

FIG. 3.—Antero-posterior view, showing replacement of fragments and plate, after operation.

FIG. 4.—Antero-posterior view, showing displacement of a fracture of the tibia.

FIG. 5.—Two screws in the tibia whose axes are oblique by rotation.

FIG. 6.—Lateral view of the same case on discharge from hospital.

FIG. 7.—Antero-posterior view. The patient was discharged from hospital to full duty.

FIG. 8.—Lateral view, after operation.

erating humidity; 2  
erating temperature;  
rage temperature;

FIG. 9.—Plaster treatment of any fracture of the lower limb, allowing the "pin" passing through the foot and a heretofore suspension bar" suspending the Thomas splint and limb.

hope. The senior family practices then were of Mr. Joseph Teale, Mr. Wheelhouse, and the brothers Price. As these gentlemen gradually retired Hall moved into the chief position, for he possessed just the blend of qualities proper for family practice; and furthermore a punctual, methodical, faithful way of quietly fulfilling his daily and hourly duties. I suspect Hall never lost a patient save by departures from the district and by deaths in the ordinary course of nature which even he was unable to prevent. Thus practice grew solidly around him. Brilliancy was not in his way, nor adventure; but he was fully competent, of large and various experience, sound in work, kindly and quietly sure of himself. Such a man wins the steady confidence of all who have need of him; and these were many. As his practice grew Hall was able to secure able partners, one of the first of them being Mayo-Robson. I remember at one of our consultations Robson confided to me his love for surgery, and his longing to risk all then present prospects in pursuit of it.

It is interesting to think how beneficent a life is that of such a family physician; for half a century perhaps the aid, the guide, and the solace of hundreds of sufferers young and old. But Mr. Hall was no less effectual as a public benefactor. He worked devotedly during the several typhus epidemics in Leeds, as I, who was then the sole Honorary Physician of the Fever Hospital, knew well. Moreover as Surgeon to the Women and Children's Hospital he was strongly moved to help children, and was, I believe, the first of those who moved in the provision of "school meals." In the joy of seeing hundreds of rosy thriving children from the slums he had his reward. And, modest as he was, one hopes that in the peace of his retirement he had some consciousness of having lived a worthy, faithful, and very useful life.

The death occurred on October 23rd of Dr. ARNOLD HEIGSORN, after an operation for appendicitis. Dr. Heigsorn was one of the Belgian refugees, who, in the early days of the war, abandoned a lucrative practice in Antwerp, where he specialized in radiology, and together with his family fled to London. Soon after his arrival he volunteered for service in the Belgian Army Medical Service, but owing to glaucoma his offer was not accepted. The condition of his eyes gradually became worse, and after several operations he was left with only a very limited visual field in his left eye. Dr. Heigsorn was a man of wide culture, and had a charm which attracted and gained the admiration and affection of all who came in contact with him, either socially or professionally. These will feel a sense of genuine sorrow at his early death. He leaves a widow and two children—a son aged 16, and a daughter 7 years old.

Professor CARL VON HESS, Director of the Munich Ophthalmological Clinic, died recently at the age of 60.

Dr. HEINRICH BIRCHER, a well known authority on military surgery and organizer of the Swiss Army Medical Corps, has died recently at the age of 73.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

At a congregation held on November 1st the degree of Bachelor of Medicine (B.M.) was conferred on A. L. B. Stevens.

*Inaugural Lecture.*—The Whitley Professor of Bio-Chemistry, Dr. R. A. Peters, will deliver an inaugural lecture in the examination schools on Wednesday, November 14th, at 5 p.m. The subject of the lecture is "A Wonderland of Chemistry."

### UNIVERSITY OF DUBLIN.

#### SCHOOL OF PHYSIC, TRINITY COLLEGE.

The following candidates have been approved at the examinations indicated:

**FINAL M.B., PART I.**—*Materia Medica and Therapeutics; Jurisprudence and Hygiene; Pathology and Bacteriology:* J. F. Wilde, T. W. MacDowell, T. C. Foster, W. J. A. McMahon, Mary C. Livingston, C. F. D. McAlidin, Gladys M. A. Lowry, W. H. Coen, P. Coleman, R. T. Cronin, Mary Galvin, G. A. Miller, J. J. Cusack, Augusta M. Young, W. O. Warrington.

*In Completion.*—G. P. Bamford, D. J. Cussen, J. Cussen, E. C. Dudgeon, C. J. du Plessis, R. W. Hart, L. W. B. Haskins, J. M.

Johnston, O. Lord-Flood, R. H. McKeag, K. F. Mackenzie, W. H. Maguire, H. M. Nevin, D. N. Power, F. M. Purcell, J. StClair, I. Strasburg, F. J. Swanepoel, C. Wilson.

**D.P.H., PART I.**—*Chemistry, Bacteriology, Physics, and Meteorology:* F. Stevenson, W. B. E. McCreagh, G. C. B. Robinson, R. Seale.

**PART II.**—*Sanitary Engineering, Practical Sanitary Hygiene, Hygiene and Epidemiology, Vital Statistics and Public Health Law:* F. Stevenson, W. B. E. McCreagh, P. M. J. Bobbett, G. C. B. Robinson, R. Seale.

\* Passed on high marks.

### ROYAL COLLEGE OF PHYSICIANS OF LONDON.

The licence of the College has been granted to C. H. Newman and Miss Muriel A. Stephens.

### ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

The following candidates, having passed the necessary examination, have been duly admitted Licentiates in Midwifery of the College: B. C. Dasgupta, Cecily M. E. Maude.

## The Services.

### No. 14 STATIONARY HOSPITAL.

The fourth annual dinner of the medical officers of No. 14 Stationary Hospital will be held on Friday, December 14th, at the Trocadero Restaurant, Piccadilly, at 7.45 p.m., under the chairmanship of Lieut.-Colonel J. R. Harper, C.B.E. The honorary secretaries are Lieut.-Colonel H. M. Perry and Dr. H. L. Tidy, 39, Devonshire Place, W.1.

### BELFAST UNIVERSITY SERVICES CLUB.

The fifth annual Armistice Dinner of the Belfast University Services Club is to be held in Thompson's Restaurant, Donegal Place, Belfast, this day (Saturday, November 10th) at 7.15 p.m. The address of the honorary secretary is University Union, Belfast. The annual general meeting of the club will be held in Thompson's the same evening at 6.30.

### DEATHS IN THE SERVICES.

Lieut.-Colonel Edward Fawcett, Madras Medical Service (ret.), died at Blackheath on November 1st. He was born on March 17th, 1847, the son of John Fawcett, of Aughtaroe, Fermanagh, and educated in Dublin, taking the L.R.C.S.I. and L.K.Q.C.P. in 1863 and the F.R.C.S.I. in 1879. He entered the I.M.S. as assistant surgeon in 1869, attained the rank of brigade surgeon lieutenant-colonel in 1894, and retired on December 28th, 1899. He served in the Burma war of 1886-87, was mentioned in dispatches in G.O.O. No. 434 of 1887, and received the frontier medal with a clasp. Major Edgar John Cecil McDonald, Indian Medical Service, died at sea on October 29th, aged 43. He was the son of the late Mr. C. E. McDonald of Baling, and was educated at King's College Hospital; he took the M.R.C.S. and L.R.C.P. in 1904. He entered the I.M.S. as lieutenant in 1905 and became major in 1915. He was serving in civil employ in Assam.

## Medical News.

A TELEGRAM to the *Times* from its Toronto correspondent announces that a committee has been formed to organize a Banting Medical Research Foundation on lines similar to those of the Medical Research Council in England. The committee hopes to raise altogether from one to two million dollars, and Dr. Banting intends to contribute 10,000 dollars out of his share of the Nobel Prize.

AN announcement appears in our advertisement pages informing those who desire to participate in the Government grant for scientific investigations for 1924 that their applications must be received by the Clerk to the Government Grant Committee, Royal Society, Burlington House, W.1 (from whom printed forms of application can be obtained), by January 1st next.

ON October 26th the Prince of Wales visited the Dundee Royal Infirmary. He was received by Mr. J. C. Bulst, president; Mr. A. B. Gilroy, vice-president; Mr. Harold S. Sharp, chairman; and Dr. H. J. C. Gibson, medical superintendent. After the presentation of members of the directorate, matron, and officials, he visited Ward 4, where Professor Stalker, Dr. L. H. Henderson, and the sister-in-charge were presented. He was thereafter conducted to a ward set apart for surgical diseases in children; Professor L. Taiton Price, F.R.C.S., Dr. James Dallas, and the sister-in-charge were presented. The Prince made special inquiries concerning the prevalence of tuberculosis, and evinced great interest in learning that the directors of the Royal Infirmary possess the Sidlaw Sanatorium, Auchterhouse, which accommodates about fifty children who suffer from this disease. The chairman pointed out the operation theatres, x-ray and electro-therapeutic departments now in course of construction, the erection of which has been made possible by the munificence of Mrs. Marryat.

Fig. 10.—Open comminuted fracture from the result of a motor cycle accident, ulnar on March 13th, 1921. Admitted on December 10th, 1921, with wounds healed and malunion, as shown in the lateral view.

Fig. 11.—The antero-posterior view of the same case after replacement of the fragments and plating on January 31st, 1922.

Fig. 12.—The antero-posterior view on discharge from hospital to his home, as a walking case, without any shortening, on March 27th, 1923.

Fig. 13.—The lateral view of the same case, showing alignment and a portion of patella and knee joint.

Fig. 14.—Antero-posterior view of a closed fracture of the lower third of femur with lateral displacement of fragments, which were entangled in muscle to such an extent as to render reduction by external manipulation impossible.

Fig. 15.—Lateral view of the same case, showing marked backward displacement of lower fragment.

Fig. 16.—Antero-posterior view after operation of wiring, combined with splinting.

Fig. 17.—Lateral view of the same case after operation of wiring; a portion of the wire loop can just be seen above the bars of the Thomas splint.

Fig. 18.—Antero-posterior view of the displacement in a closed fracture of the femur involving the knee joint.

Fig. 19.—Antero-posterior view of the replacement and the fragments held together by means of a plate, screws, bolt, and nuts.

THE Fellowship of Medicine and Post-Graduate Medical Association has arranged a refresher course in general medicine and surgery from December 3rd to 15th at the Hampstead General Hospital, with which will be associated the Hospital for Epilepsy and Paralysis, the North-Western Fever Hospital, and Paddington Green Children's Hospital. The course will be a whole time one, and will include work in all departments. There will also be a course in neurology at the Hospital for Epilepsy and Paralysis, Maida Vale, of which further particulars will be announced later. Full information can be obtained from the Secretary to the Fellowship of Medicine, 1, Wimpole Street, W.

THE annual dinner of the Cambridge Graduates' Club of St. Bartholomew's Hospital will take place on Wednesday, November 21st, at 7.30 p.m., at the Hotel Victoria (King Edward VII Rooms), with Dr. W. Langdon Brown in the chair. The honorary secretaries are Dr. H. N. Burroughes and Mr. Reginald M. Vick.

THE Glasgow University Club, London, will dine at the Trocadero on Thursday, December 6th, at 7.30 p.m., when Lieut.-General Sir W. B. Leishman, K.C.M.G., F.R.S., will be in the chair. Any Glasgow University men, not members of the club, who would like to attend are requested to communicate with the honorary secretaries, 1, Harley Place, N.W.1.

THE first Lloyd Roberts Lecture at the St. Mary's Hospitals, Manchester, will be delivered by Professor A. Donald, M.D., on Friday, November 23rd, at 5 p.m., in the lecture theatre. Members of the medical profession are cordially invited to attend.

AT a sessional meeting of the Royal Sanitary Institute at the Town Hall, Ipswich, on Saturday, November 17th, at 10.30 a.m., discussions will take place on sewage disposal and on tuberculosis in milk. In the afternoon visits will be paid to various municipal undertakings.

AT the opening meeting of the Illuminating Engineering Society to be held at 8 p.m. on Tuesday next (November 13th) at the Royal Society of Arts reports will be presented on recent progress, and a number of novelties, including the Irwin colour filter system and new types of motor-car head lights, will be exhibited.

WE are asked to announce that a concerted effort on behalf of the British Empire Cancer Campaign is being made throughout the Dominions. The Wellington (N.Z.) Branch of the British Red Cross Society reports that an intensive "cancer campaign" has been organized for the middle of this month in the city. The co-operation of the Newspaper Proprietors' Association has been secured and permission has been given to advertise the campaign free of cost on the tramways. In this country a continuous flow of subscriptions is reaching the offices of the British Red Cross Society. Contributions should be sent to the Hon. Sir Arthur Stanley, British Red Cross Society, 19, Berkeley Street, London, W.1, or to any of the branches of Lloyds Bank.

THE opening of the new school of dental surgery at King's College Hospital will take place at Denmark Hill on Monday, November 12th, at 4.45 p.m. The inaugural address will be given by the Right Hon. F. Dyke Acland, M.P., chairman of the Dental Board.

DR. A. V. HILL's inaugural lecture as Jodrell Professor of Physiology at University College, London, on "The Present Tendencies and the Future Compass of Physiological Science" will shortly be published by the University of London Press.

THE Manchester Children's Hospital, by special permission of the King, will in future be known as the Royal Manchester Children's Hospital.

A PAPER communicated to the Royal Society by Professor T. B. Wood on November 1st reported some experiments by Mr. T. Deighton which led to the conclusion that the basal metabolism of a pig from 75 days upwards was greater in mid-youth than at any other time of life, and that the metabolism after the ingestion of food reaches a maximum after five hours and then declines. A curve of basal metabolism showing its variation with age favoured the conclusion that the increase of metabolism in youth is directly ascribable to growth. In this respect also the pig seems to resemble man.

THE Catherine Gladstone Home at Mitcham has been brought up to date by the Marie Celeste Samaritan Society of the London Hospital, which will maintain and manage it as an annexe of the hospital. It will be formally opened by the Minister of Health at 3 p.m. on Monday, November 19th.

DR. T. P. THOMAS of Brecon was entertained at dinner on October 25th in recognition of his valuable services as honorary secretary of the County Panel Committee, and to commemorate his occupancy of the office of high sheriff. He was also presented with an inscribed silver coffee tray from his medical colleagues.

THE Prince of Wales, as President of the Royal Northern Hospital, Holloway, will open its new casualty department (which is the war memorial of the borough of Islington) on November 27th. Contributions amounting to £12,000 have been received towards the cost of the department, but a further £4,000 is required to open the building free of debt.

THE first lecture of the one hundred and seventieth session of the Royal Society of Arts will be held on Wednesday next, November 14th, at 8 p.m., when M. Edouard Belin will give an address on the electric transmission and reproduction of writing, designs, and photographs without wires. On November 28th Sir H. J. Gauvain will speak on the effect of sun, sea, and open air in the treatment of disease; and on December 5th Dr. A. W. Hill, F.R.S., Director of the Royal Botanic Gardens, Kew, will give an account of the work done there.

THE annual dinner of the London (Royal Free Hospital) School of Medicine for Women will be held at the Savoy Hotel on the evening of Thursday, December 6th.

THE annual dinner of the past and present students of the Royal Dental Hospital of London will be held at the Trocadero Restaurant on Saturday, November 24th, at 6.30 p.m. for 7 precisely, when Mr. G. Northcroft, O.B.E., will preside.

AT the meeting of the Tuberculosis Society to be held at the Margaret Street Hospital, London, W.1, on November 16th, at 8 p.m., Professor Leonard Bernard will give an address on tuberculosis in France.

A MEETING of the Medico-Psychological Association of Great Britain and Ireland will take place on Thursday, November 22nd, at 11, Chandos Street, Cavendish Square, W.1. The chair will be taken by the President, Dr. Edwin Goodall, C.B.E., at 2.45 p.m.

DR. HENRY SALOMON of Leicester has, for the second time been awarded, by the Ministry of Health, a Government grant for successful vaccination.

WE are asked to state that the *Textbook of Pathology* by Delafield and Prudden reviewed in our issue of November 3rd (p. 818) is issued in this country by Messrs. John Bale, Sons, and Danielsson.

UNDER the will of Miss Florence Carver, whose father was for many years prominently associated with the Nottingham lace trade, the Nottingham General Hospital will receive a legacy of £40,000.

THE "Toll" system of dealing with short-distance trunk calls, introduced by the Post Office some time ago, has resulted in a marked growth in the traffic. The average daily number of calls to places within the area now covered by the "Toll" exchange was 14,000 before the introduction of the "Toll" system, and it is now 24,500. The Post Office asks us to state that some hundreds of demands are still made each day for "Trunks," although the exchange required is reached by the "Toll" system. It is in the interests of telephone users to avoid the delay thus caused; they are therefore advised to consult the list of exchanges in the "Toll" system shown in the preface to the London Telephone Directory before asking for a short-distance call.

THE Senate of Uruguay recently confirmed a revaccination bill making revaccination obligatory every ten years.

THE fiftieth anniversary of the founding of the New York Laryngological Society will be celebrated on November 15th. This organization, now the Section in Laryngology of the Academy, is believed to be the oldest society in existence of the department which it represents. In connexion with the celebration there will be an exhibition representing the important contributions made to the progress of laryngology in the city of New York.

THE twentieth congress of the Italian Society of Dermatology and Syphiligraphy will be held in Rome from December 20th to 22nd. The subjects to be discussed are herpes (Dr. Mariani) and the various preparations of bismuth in the treatment of syphilis (Dr. Trulli). Further information can be obtained from the secretary, Dr. V. Montesano, Via Campo Marzio 69, Rome.

THE two hundredth anniversary of the death of the celebrated anatomist Antonio Maria Valsalva was celebrated on September 23rd at his birthplace, Imola, in Northern Italy.

DR. L. EMMETT HOLT, vice-president of the American Child Health Association, has been appointed visiting professor of pediatrics to the Peking Union Medical College by the Rockefeller Foundation. Dr. Holt is to conduct a three months' course of lectures, introducing the latest methods in the treatment of child diseases to Chinese medical practitioners.

THE Department of Health of New York City has prohibited the retail sale of veronal, veronal sodium, luminal, luminal sodium, sulphonal, trional, or tetralon except on the written prescription of a registered medical practitioner.

hair, some of which hairs are found in its faeces. Under the long unpigmented hair of the winter coat, short pigmented hairs are to be found.

*Loss of the Pigmented Hair in Grey Horses followed by Melanoses.*

Grey horses after the age of ten years tend to become white owing to the loss of pigmented hair, including the hair of the mane and tail. With increasing age these animals develop some form of melanotic cancer with such increasing frequency as to give rise to the statement that a white horse lives long enough some degree of melanotic new growth will be found on a complete examination after death.

The skin covered by the white hair is likewise unpigmented, but the pitch-black pigmented skin, free from hair, of the ano-genital region, mammae, scrotum, and folds of the prepuce, also the margin of the lower lip, remain unaltered. This deeply pigmented hairless skin is a site of predilection for the starting of melanotic disease (Fig. 11). It is first noticeable as small black nodules which run together into tumours and then come to be embedded in a general thickening which later has the characteristic appearance of rugose elephantiasis. Preceding this naked eye appearance there have been found microscopic changes, when vertical sections are made through the skin under the tail of an aged white horse isolated pigmented spots may be seen, in particular near the deep curled ends of the sweat glands (Fig. 12). On the other hand, examination of the same skin taken from an old horse which has retained pigmented hair fails to discover such collection of pigmented cells. The melanotic disease does not extend superficially beyond the black hairless areas, but removal is only practicable in the case of melanotic elephantiasis of the folds of the prepuce. The inguinal glands enlarge early, but remain circumscribed and do not infiltrate. The two commonest external manifestations of secondary disease are in the parotid region, and between the scapula and spine, deep in the rhomboid muscles. Similar instances occur in human beings; a case of scapular metastasis was described by Cairns.

From the ano-genital and inguinal regions the disease spreads to pelvic and lumbar glands, to the abdominal and thoracic viscera. Black cords and chains of nodules are found in the retroperitoneal tissue, masses in the spleen, etc., at the root of the lungs, and around the base of the heart. There is a marked absence of general wasting, the animal working until it dies suddenly. The enormous growths cause mechanical obstruction by displacement of tissues without general infiltration. Whilst in human beings the growths commonly remain solid, in horses they are often cystic. Haycock wrote his note with the black fluid contained in one of the cysts, just as Currier driver a sepal with the animal's milk. A cystic tumour of the spleen or lung may rupture and cause immediate death of the horse.

Pigmented naevi exhibit melanin granules in the basal layer of the epidermis, and to a variable but much smaller extent in the rete spinosum. Moles which are rugose on the surface have fewer rows of cells in the rete spinosum, and an increased thickness of the cornuous layers. The original structure of the pigmented naevus consists of a regular arrangement of cells, the epidermis being clearly distinguished from the dermis. During adult life there is a slow degeneration, variable in degree, to be recognized by a full examination of a number of specimens.

The epidermis and dermis become less sharply defined; there are branched pigmented cells in the dermis, some are epithelial cells which have dipped down, some connective tissue cells which have taken up pigment freed by the breaking down of epithelial cells (Fig. 13). Free granules of pigment are found in lymphatic spaces and cells may have a dusky stain. These changes are to be noted before any sign of cancer, but also in the areas surrounding the commencement of cancer.

The malignant growth begins in the lowest layer of the epidermis, and resembles either one of the varieties of rodent ulcer or squamous-celled carcinoma. Just as sections of chimney-sweeps' cancer show granules of soot in the cells of the malignant growth begins in the lowest layer of the epidermis, but also in the areas surrounding the commencement of cancer.

The original structure of the pigmented naevus consists of a regular arrangement of cells, the epidermis being clearly distinguished from the dermis. During adult life there is a slow degeneration, variable in degree, to be recognized by a full examination of a number of specimens.

growing downwards, so also in melanotic cancer the growing margin of cells exhibits melanin granules. As the epithelial cells grow down into the dermis they tend to assume an oval or spindle shape (Fig. 14), later on an alveolar arrangement; they break into lymphatics, invade the wall of blood vessels, and set up haemorrhage.

The masses of melanotic cancer in lymphatic glands and internal organs are composed of oval and spindle cells. Whilst recent observations indicate epidermal cells as those which commence the malignant change, the appearances of the tumours have led them to be termed sarcomata. Page, in his lectures, generally used the term "melanotic cancer," and I have followed him in that respect. Discussion has proceeded much on the same lines as earlier debates concerning the origin of the elements composing a sarcoma-cancer of the breast, also as regarded the cancers produced by rubbing tar into the ears of animals.

Melanomas are very common among darker races, indeed more so than among white races, yet this does not render them prone to melanotic disease. No great stress can, perhaps, be laid on this point, because such races are generally reported to be less susceptible to cancer in men and women. Yet no case was seen or heard of in which a pigmented mole had tended to spread or give rise to tumour formation. Among 8,000 hospital surgical in-patients belonging to dark races in Constantinople there were 390 cases of carcinoma, 125 of sarcoma, and 5 of melanotic cancer; two of the latter had grown from the relatively unpigmented sole of the foot, and one involved the gall bladder after the patient had suffered from what had been called piles. Among 12,000 surgical out-patients there were no cases; among 2,000 eye cases there were two— one originating in the conjunctiva, the other in the ciliary body. The occurrence seems likewise rare among negroes in the United States; the only case I have noted, one described by Gilchrist, began on the relatively unpigmented sole of a negro, as in the two Constantinople cases.

An exceptional case was seen by me in conjunction with Dr. Redmond Roche. A boy aged 5 was the son of brunette parents, both of whom presented numerous superficial pigmented moles; on the dorsum of one of the boy's toes was a superficial ulcer with a black surface which had been treated as a chancre. Examined after excision the ulcerated mole exhibited pigmented enlarged haemorrhages in the base of the ulcer; the corresponding enlarged gland showed foci of pigmented cells and haemorrhages. The other two proved to be quiescent epithelial melanomas. I cannot give a subsequent report on the case, but at such an age malignant disease may be considered out of the question.

Pigmented spots acquired after puberty or late in life may also become malignant. Hutchinson described several melanotic whitlows; many more instances have been described since that date, all remarkably alike, and all pursuing a malignant course (Fig. 15). They are instances of melanotic squamous-celled carcinoma. The specimen described by Bowdler occurred on the great toe—half is in the College Museum, half in that of St. Bartholomew's Hospital. In Casati's case the toe-nail from childhood had separated on many occasions before melanosis set in.

Hutchinson also described the senile freckles, lentigo senilis, which occasionally become malignant. The clinical course and structure of the growth is then as a rule that of rodent ulcer followed ultimately by a metastasis. A slight puncture of the skin may leave a pigmented spot which subsequently becomes the seat of melanotic cancer. In Eve's case a woman at the age of 27 ran a splinter into the hypothenar eminence, and a black spot persisted there for twelve years, until after being again accentedally pricked. Melanotic cancer then started, of which she died eleven months later. Two of the Museum specimens are from a man aged 55 in whom melanotic cancer superimposed from a puncture by a horn under the jaw three months before. The man died of the disease fifteen months after the injury.

Once the malignant change has started metastasis follows, whether it becomes apparent soon or late; there are extra-

Metastasis of Melanotic Cancer.

Metastasis of Melanotic Cancer.

## 6. Cerebral Tumour Simulating Lethargic Encephalitis.

H. CLAUDE, H. SCHAEFFER, and T. ALAJOUANINE (*Paris méd.*, April 14th, 1923, p. 337) record the case of a woman, aged 49, who presented symptoms of somnolence and stupor accompanied by diplopia and ptosis, followed by a certain degree of rigidity resembling post-encephalitic Parkinsonism. Headache did not occur until four days before death, and there was no vomiting; the fundus was not examined. Death, which took place four days after lumbar puncture, was probably due to haemorrhages within the tumour caused by sudden decompression. The autopsy showed a large glioma in the right cerebral hemisphere invading the lenticular nucleus, optic thalamus, internal capsule, cerebral peduncle, and third ventricle. In their comments on the case the authors remark that the opposite error may be committed, epidemic encephalitis being mistaken for cerebral tumour. Sands reported three cases of encephalitis with papilloedema at first diagnosed as cerebral tumour in which the favourable issue revealed the true condition. E. Farquhar Buzzard and J. G. Greenfield (*BRITISH MEDICAL JOURNAL*, November 20th, 1920, p. 782) have shown that the principal symptoms of lethargic encephalitis are merely due to their localization, and are not, properly speaking, specific. The diagnosis between cerebral tumour and lethargic encephalitis is to be made by the coexistence of other evidence of infection, and especially by the course of the disease. Papilloedema is frequent in cerebral tumour and rare in lethargic encephalitis, and the cerebro-spinal fluid is under tension in cerebral tumour but not so in encephalitis.

## 7. The Treatment of Vasomotor Rhinitis.

J. KRAGH (*Ugeskrift for Læger*, May 10th, 1923, p. 339) has treated with success three cases of vasomotor rhinitis on the assumption that this condition is an anaphylactic phenomenon comparable with hay fever and asthma. He gave small quantities of a non-specific protein, choosing peptone for this purpose. The first patient was a woman, aged 25, who for several years had suffered from attacks of sneezing, itching in the nose, a watery secretion from it, and periodic obstruction. Though she could not eat eggs, which made her skin itch, withholding eggs from her dietary did not affect the nasal symptoms. She was given 35 cg. of peptone half an hour before each of her three meals, and after a couple of days all the symptoms disappeared. This treatment was continued for ten days. After it had been discontinued for another ten days the symptoms returned, and giving peptone by the mouth now proved futile. She was, therefore, given it by intramuscular injection, 5 grams of peptone in saline solution being injected once a week for five weeks. After the first injection the symptoms disappeared completely, and she regained the sense of smell which she had lost for several years. When the treatment was discontinued she relapsed, but the symptoms were not as severe as before. In the two other cases the beneficial results lasted much longer, and one of the patients was still symptom-free six months after the institution of treatment.

## 8. Angina Pectoris.

J. PAL (*Wien. Arch. f. innere Med.*, Festnummer, Bd. VI, Heft 1, 1923, p. 153) discusses the cause, symptoms, and treatment of angina pectoris, and states the conclusions drawn from his own experience in a large number of cases. He regards angina pectoris as an angiospastic crisis in the region of the coronary vessels and the root of the aorta. The special excitability of this region is, he believes, brought about by changes such as mesoarteritis, arterio-sclerosis with obstruction of the orifices of the coronary arteries, endocarditis of the aortic valves, or may be only functional. When this special excitability exists, psychical excitations or sensory irritations (cold and pain) are easily reflected on this critical zone. The attacks are accompanied by circulatory phenomena, vascular crises with increased blood pressure, or cardiac crises. Only in very exceptional cases is a sinking of the blood pressure observed. The vasomotor nature of the attacks is indicated not only by the prompt action of drugs causing dilatation of the coronary arteries (caffeine, theobromine, atropine), and of general antispasmodic drugs (papaverin, akineton, and nitrites), but also by the influence of warmth and fever. In one of the cases which the author records in detail the effect of febrile conditions in always arresting the attacks temporarily was clearly shown. In the treatment of angina pectoris the author attaches much importance to warmth, and especially to the drinking of hot water. If this fails he regards the intravenous injection of certain drugs as the most suitable treatment on account of their immediate action. He recommends papaverin, akineton, and novatropine, and a combination of papaverin and novatropine (troparin), which may be injected intravenously without danger.

## Surgery.

### 9. Perforation of Gastric Ulcer by Stomach Tube.

THAT gastric lavage, or even the passage of a stomach tube for a gastric analysis, may be a dangerous procedure in the presence of a chronic perforating type of ulcer, and that the trauma arising from the use of the stomach tube may cause an acute perforation of a chronic ulcer, is shown by a case reported by G. SCHWARTZ (*Journ. Amer. Med. Assoc.*, May 26th, 1923, p. 1520). Because of pain in the pit of the stomach, a physician advised gastric lavage. When the stomach tube was passed, the patient had an agonizing pain in the pit of the stomach, and felt faint. The tube was withdrawn and the patient allowed to recline for a while, after which he felt slightly better. He was then taken home and given a hypodermic injection (presumably morphine), and spent a fairly comfortable night. On arising in the morning he felt weak and had a slight pain in the pit of the stomach. For breakfast he had two soft-boiled eggs, one biscuit, and a cup of warm milk; in a few minutes he fell to the floor with a cry of agony and fainted. When the author saw him the patient was in profound shock, and the abdomen presented a typical picture of perforated ulcer. The abdomen was opened; it was full of a sero-purulent fluid; the eggs and milk which the patient had had for breakfast were free in the abdominal cavity. There was a large perforation, which easily admitted the ring finger, and which was large enough to admit a stomach tube on the anterior wall of the stomach near the lesser curvature, and about 2½ inches from the pylorus. The gastro-hepatic omentum had made a feeble attempt to encircle the perforation, which, however, was too large to permit its being sealed from the general peritoneal cavity. The perforation was closed with a double purse-string suture and a piece of the gastro-hepatic omentum sewn over it for added protection. No gastro-enterostomy was done because the patient seemed moribund. All the fluid in the peritoneal cavity was aspirated with the suction apparatus, one drain being placed in the kidney pouch, and another in the pelvis through a suprapubic stab. The patient received nothing by the mouth for five days, but was given 1,500 c.cm. of physiological sodium chloride solution subcutaneously daily, with a continuous rectal drip of 5 per cent. glucose and sodium bicarbonate; he was permitted fluids by the mouth on the sixth day. He made an excellent recovery and was out of bed and taking a soft diet on the thirteenth day.

### 10. The Surgical Treatment of Infantile Paralysis.

CAPRIOLI (*La Pediatria*, April 1st, 1923, p. 382) says the aim of treatment in post-paralytic equino-varus is (1) to re-establish the equilibrium of the antagonistic muscles, and (2) to bring the foot back into the best possible position. Whereas many surgeons prefer to straighten the deformity first and then deal with the muscles by transplantation of tendon, or otherwise, the author says that he gets better results by first treating the muscles and tendons, and then, three or four weeks later, he proceeds to forcible straightening. This is done in four stages: (1) Dorsiflexion of the foot, (2) external rotation with the os calcis fixed, (3) forcible pronation, and (4) straightening of the plantar arch. Photographs are given of the various manoeuvres, and details of 8 cases so treated are added, with a bibliography of 36 references to recent literature on the subject.

### 11. Cholecystectomy for the Sterilization of Typhoid Carriers.

C. ARND (*Schweiz. med. Woch.*, April 26th, 1923, p. 423) has attempted to stamp out an endemic of typhoid fever in an asylum by performing cholecystectomy on certain of its inmates. Altogether 15 typhoid or paratyphoid carriers were thus treated, and 8 out of 10 typhoid carriers were found no longer to harbour typhoid bacilli in the stools after the operation. None of the 5 paratyphoid carriers was sterilized by this operation, and, curiously enough, two persons who had been typhoid carriers before the operation, and who ceased to be so after it, were now found to be paratyphoid carriers. An observation which somewhat detracted from the reputation of cholecystectomy for this condition was the finding that the gall bladders of four of the typhoid carriers were perfectly sterile. This was also the case with three of the five paratyphoid carriers. As the author points out, it is difficult to account for the disappearance of typhoid bacilli from the stools of a person whose gall bladder has been found to be sterile on removal. This experience suggests that patients may often cease to be carriers spontaneously, and that good results have been claimed for cholecystectomy in a certain number of cases in which the same result would have occurred had no operation been undertaken.

ordinary instances of delay in its appearance. Coley reported 91 cases treated by excision, also by his toxins, radium, and x rays. The primary treatment of a pigmented mole which had begun to spread failed, whichever of the above means was used.<sup>43</sup> In Küttner's Klinik from 1890 onwards there were 39 cases of melanotic cancer. Of 26 submitted to operation 4 survived the first operation for five years, soon after which 3 died of generalized melanotic cancer.

A few individuals appear to present an extraordinary resistance to the extension of the cancer.<sup>45</sup>

Chauvin operated four times upon a woman in the course of twenty-two years.<sup>44</sup> At the age of 28 a brown mole which had ulcerated was removed from the right naso-labial furrow; it exhibited under the microscope the structure of melanotic cancer. Four years later a similar nodule was removed from the right malar region, and two years subsequently a further recurrence at the same spot. For the fourth time, the patient being then 48, two nodules of melanotic cancer, placed on the line of the lymphatics in the course of the facial artery, were cut out. There was then no sign of lymphatic gland enlargement or of metastasis.

Eve<sup>43</sup> described the case of a woman who twenty years before had a melanoma cut out from the dorsum of the hand. There was a recurrence *in situ* ten years later, and a second recurrence at the end of twenty years, when there were in addition metastatic growths in the axilla and on the temple.

Mr. Jonathan Hutchinson, junr., verbally informed me that he saw a woman who for ten years had discharged a melanotic fluid from the stump after the removal of the eyeball by Tay for melanotic cancer.

A widely diffused pigmentation of the skin has occurred in the course of generalized melanotic cancer. Cases have been described by Fergusson, Legg, Matsunga,<sup>47</sup> and Tietze. Such increased production of melanogen and melanin has been previously emphasized.

#### *Melanotic Cancer of the Eyeball.*

Both in men and animals there occur abnormalities of pigmentation in all grades down to complete albinism. The parti-coloured iris is a slight abnormality; the so-called "wall eye" is common in the horse, and includes a greater abnormality affecting the uveal layer in the choroid and ciliary bodies. But in the most complete albinism the retinal pigment epithelium is constantly normal.<sup>4</sup>

Mr. Foster Moore, in the course of routine examinations of the ocular fundus, has noted patches of pigment, which, however, had given rise to no defects of vision. The patches are situated near the optic disc not more than two diameters of the disc away, having an area of a quarter to four times that of the disc. They have a homogeneous colour, likened to that of blue ointment, an oval or circular contour, and a feathered edge with the retinal vessels, normal in character, crossing in front. One patch examined *post mortem* showed a structure corresponding with a mole on the skin, and so these patches appear to be congenital in origin. The patches remained quiescent under observation, and no relationship with melanotic cancer has been established.<sup>48</sup>

In spite of the frequency of "wall eye" in horses, a melanotic cancer of the eyeball is rare even in the grey horse which turns white.

Melanotic cancer arises in the eyeball as a rule after middle life. Whilst it generally arises from the pigmented layers within the eyeball, it may start external to the eyeball in the conjunctiva or eyelid, when it may be in a congenital or acquired spot of pigment.<sup>52</sup> It has often followed upon an injury, but the onset may be delayed.

In Lawson's case the eyeball had been injured and shrunken for twelve years.<sup>49</sup> In Keown's case the patient had been for long exposed to an excess of electric light.<sup>50</sup> In Pfingst's case the disease occurred in two brothers;<sup>51</sup> in Silcock's in a mother and daughter. In Robinson's case a pigmented spot appeared on the outer surface of the upper eyelid and gradually spread over the forehead and cheek; later there was extension to the mucous membrane within the cheek and to the opposite eyelid.<sup>53</sup>

Melanotic cancer as a rule has advanced so far before the eyeball was removed that patients have died of metastasis even although there has been no recurrence *in situ*. The usual course is for a secondary mass in the liver, etc., to be attended by melanuria and to cause the patient's death within three years.<sup>54</sup> Death may, however, be delayed; there may even be extraordinary delay—namely, for 10, 12, 16, 17, and even 24 years in Olbert's case.<sup>55</sup> Except after melanotic growths of the eyeball, melanotic

cancer of the liver with melanuria is rather the exception, otherwise one might almost believe such prolonged intervals to indicate an origin *de novo*.<sup>56</sup>

#### *Melanoma and Melanotic Cancer of the Hard Palate.*

Congenital patches may be noted on the hard palate, also on the inner aspects of the cheek and tongue in dark races—for example, Dravidian races in India. They have also been stated to appear for the first time in middle life and afterwards to spread. When cut out early the structure is found to be that of quiescent melanomas. More than twenty-five cases have been recorded of melanotic cancer of the hard palate. Treatment by excision, x rays, radium, diathermy have all alike failed to arrest the spread of the disease.<sup>57</sup>

#### *Melanotic Cancer of the Abdomen.*

Melanotic cancer in the abdominal cavity is usually secondary. As to a primary origin in the abdomen recorded cases have not been completely investigated—for example, as to the possibility of a supposed benign mole in the skin having undergone a malignant change discoverable only by microscopic examination. With this reservation melanotic cancer has been described as arising in the suprarenal capsule on one or both sides, in the ovary, urinary bladder, and gall bladder. The general explanation would be that the origin has been in one of the congenital patches of pigment which have been classified as perineural, perivascular, pericoelomic.

#### *Melanoma and Melanotic Cancer in the Ano-genital Region.*

This is an area which exhibits some pigmentation even in blond races. Pigmented moles are common on the external genitals of dark women, and in Indian women pigmented patches have been noted on the wall of the vagina and cervix uteri. Eardley Holland collected fifty-two cases of melanotic cancer of the vulva, of which number only one woman was free from signs of recurrence after three years.<sup>58</sup> A melanotic cancer of the vulva may be secondary; in Doran's case it followed upon an adrenal tumour, and he included references to two similar cases. A melanotic cancer of the penis is of rare occurrence: Shattock showed how readily the unpigmented glands of the negro becomes pigmented when uncovered. Primary melanotic cancer of the anus has been in its earlier stages confused with piles. In the negro the pigmentation of the skin is sometimes continued irregularly within the anus, and such an explanation may be given of the starting of a melanotic cancer in the rectum.<sup>59</sup> In Heaton's Museum specimen a man aged 48 had had haemorrhoids for twenty-five years when melanotic cancer set in, and after his death seven months later there were found invasion of lymphatic glands and a nodule of melanotic cancer on the surface of the liver.

#### *Perineural Melanotic Cancer in the Pia Mater of the Brain and Spinal Cord.*

In a few cases it has been possible to define the situation in which the growth started. In Hirschberg's case it commenced at the level of the eleventh dorsal vertebra,<sup>63</sup> in Ogle's case in the pineal body, when the pigment may be related to the so-called median eye of the lizard *Hatteria* or *Sphenodon*.<sup>60</sup> MacLachlan described an extensive pigmentation associated in children with multiple pigmented naevi on the skin.<sup>61</sup> There were small pigmented nodules the size of millet seeds scattered along the course of the blood vessels of the pia mater and of the ependyma of the ventricles.

Generally at *post-mortem* examinations melanotic cancer has been found widely disseminated in the pia mater with multiple tumours, when it has not been possible to identify the actual starting point (Fig. 16). There has been a relative absence of signs, largely due, as in Babinski's case, to the growth not infiltrating but displacing the original tissues.<sup>62</sup> I exhibit specimens in which it was impossible to discover the seat of origin of the disease.

A woman, aged 36, had suffered vaguely in her head for four months. On admission to the Westminster Hospital a diagnosis of increased intracranial tension from multiple new growths was made. The patient was not relieved by decompression. The pia mater over the under surface of the medulla, pons, cerebellum,

In the report of the War Office Committee on Shell Shock, 1922, it is recommended that only fit men (Grade I) as judged by the pre-war standard should in future be enlisted into the regular army. It is, however, obviously of great importance to be able to estimate not only a man's physical condition at the moment, but also the likelihood of his maintaining bodily endurance when exposed to physical strain. This is particularly the case in respect of officers of the Royal Air Force; at the end of 1916, for instance, the carrying of aerial warfare to higher altitudes imposed additional strain on pilots, and breakdown became more frequent. In order to ascertain whether such an estimate could be made by means of medical examination, a special investigation was undertaken under the auspices of the Medical Research Council, and it was shown to be possible to differentiate the fit man who is likely to endure from the man who either will not stand strain well or will inevitably break down under it. These results form in large part the basis of the method of selection in the Royal Air Force to-day, and corroborative evidence of their value is continually forthcoming. It is now possible not only to exclude those who are physically unfit for the arduous duties of flying and combatant service, but also by periodic examination to withdraw from service such as are in need of rest, at a stage before real breakdown has occurred.

Full details of the routine tests now in use, other than those employed for the classification of special conditions, are given in the official Air Ministry publication dealing with the medical examination for the Royal Air Force. These tests in no way displace the general clinical examination, but merely serve as adjuncts thereto.

The chief points to which attention must be paid in the assessment of physical efficiency and bodily endurance are—(1) respiratory efficiency, (2) circulatory efficiency, and (3) general nervous stability as regards control through the centres of respiration and circulation, and cerebral and psychological control.

**Respiratory Efficiency.**—The practice of measuring the upper chest expansion on inspiration should be abolished or at least combined with a measurement at the level of the floating ribs, which is more important. Correct inspiration consists in the contraction of the diaphragm attended with an upward movement of the lower ribs, and is the type prevalent in individuals who possess the greatest bodily endurance. If inspiration be properly performed correct expiration naturally follows, but it should be borne in mind that expiration is under muscular control, and it has been shown that it is on the expiratory rather than the inspiratory side that individuals tend to fail as the result of strain. With regard to the value of spirometry in the assessment of physical fitness there is no doubt that the usual instrument gives very inconsistent results, and there is, moreover, still a divergence of opinion as to what constitutes the normal vital capacity. It is, however, a distinct advantage to be able approximately to estimate the vital capacity, and for this purpose the author compares Dreyer's tables with one prepared from the results of Cripps, Greenwood, and Newbold. In this way an idea is obtained as to what vital capacity should be for the standing height, sitting height, weight, and chest circumference of the individual in regard to Dreyer's figures. The vital capacity should equal his Class A, or, preferably, exceed this class by 300-500 c.c.m. When the vital capacity falls much below this, respiratory insufficiency is certainly present. Observation proved that officers who could not fly high possessed a small vital capacity, and especially those who were suffering from flying strain. In the latter the diminution in vital capacity was shown to be due to an inability to expire sufficiently to empty the lungs to the full extent. The fit individual is possessed of a good vital capacity mainly because he has this power of adequately emptying his lungs by expiration. In the individual who is respiratorily inefficient the vital capacity is considerably reduced by prolonged physical effort and his "ventilation capacity" is decreased (residual air increased, and the ratio of vital capacity to residual air diminished). Thus the respiratorily fit person is one who, in response to physical effort, is able to maintain his "ventilation capacity" at a relatively high level over the whole period of performance.

**Diminution in ventilation capacity.** Diminution in ventilation capacity is a relatively high level over the whole period of performance. Thus the respiratorily fit person is one who, in response to physical effort, is able to maintain his "ventilation capacity" at a relatively high level over the whole period of performance.

Further involves a relative increase of carbon dioxide and decrease of oxygen in the alveolar air.

The partial pressure of carbon dioxide and oxygen plays a considerable part in determining the time over which an individual can hold his breath. In the fit subject it requires a considerably greater diminution of the partial pressure of oxygen to induce symptoms of respiratory instability and circulatory embarrassment (violent desire to breathe, quickened heart rate, increased blood pressure, congestion of the face) than in one who is suffering from fatigue or lowered efficiency. Similarly with an increased percentage of carbon dioxide. Both the 40 mm. Hg test and the breath-holding test may, therefore, be taken as affording indications of the ventilation capacity of the individual and of his susceptibility to changes in the alveolar partial pressures. Stable control by the respiratory centre is an important factor in bodily endurance, and the above tests are of value in assessing respiratory efficiency in this respect. In an individual of adequate respiratory capacity the time of holding the breath without undue discomfort is, in the breath-holding test, 69 seconds; in the 40 mm. Hg test, 50 to 55 seconds. The expiratory force test is of value as showing the condition of the expiratory musculature; generally respiratory insufficiency is indicated when the reading falls below 110 mm. Hg, and it is certainly significant of general physical inefficiency when it fails to reach 80 mm. Hg.

**Circulatory Efficiency.**—A pulse rate, at rest, above 84 (not due to temporary excitement) is characteristic either of nervous instability or of physical inefficiency. As regards the latter, it was found, for instance, that by special exercises for one month the average standing pulse rate of a number of "weedy" recruits was reduced from 95 before training to 79 after training. A quick pulse rate (66 or above) is frequently an expression of nervous instability, particularly a quick pulse associated with a respiratory rhythm. Such persons are not, generally speaking, suitable for arduous services, and frequently break down.

The arterial pressures afford important information. If, in the absence of any clinical signs of disease in a person of 20 to 25 years of age, the systolic and diastolic pressures are persistently high, and the pulse pressure exceeds 50 mm. Hg (for example, SP 160, DP 104, PP 56), the individual may be regarded as having a "nervous temperament" and as not likely to stand great physical and mental strain. In certain cases such pressures are due to excessive indulgence in alcohol over a prolonged period, and the other tests for physical efficiency, particularly those for nervous stability, will then be found to give unsatisfactory results. As regards low diastolic pressures, or below 70 mm. Hg, is combined with a pulse pressure of more than 50 mm. Hg, indicative of lack of physical stamina for flying duties. Such subjects are particularly liable to faint in the air, and the same holds true to a less extent as regards physical endurance on the ground. The fit individual is one in whom the margin of fall of the diastolic pressure is in the neighbourhood of 30 mm. Hg (that is, a diastolic pressure of 80 mm. Hg) before the fainting pressure is reached. In subjects with a low diastolic pressure a contributory factor of great importance, and one that is insufficiently appreciated, is the accumulation of blood in the abdominal veins put is reduced and becomes insufficient to maintain an adequate diastolic pressure, although the arterial system pressure remains normal. As affording information of this condition the pulse response during the 40 mm. Hg test is of great service. In a fit subject there is little alteration of the initial pulse rate over a period of fifty to sixty seconds, and the arterial pressure are not greatly raised on the other hand, the test produces a greater and more rapid elevation of the arterial pressures (for example, to 180-200 mm. Hg), while the pulse rate rapidly increases to 120-130 or more. This increase is maintained when the total rise of pressure is not abnormally high, but is succeeded by a marked and often abrupt fall of pulse rate when the arterial pressure is increased to a high point—for example, 220-240 mm. Hg, a point which appears to be constant for each individual. The fall is possibly due to

and olfactory lobes presented a dark brown greenish staining. The cortex of the cerebrum, pons, and cerebellum under the pia mater exhibited numerous black nodules and spots. There were melanotic tumours in the base of the left lung, in the liver, in the retro-peritoneal tissue, and adherent to the outside of both suprarenal capsules, the substance of these organs being unaltered.

#### Melanotic Cancer in the Olfactory Mucous Membrane.

I have already stated that melanin pigment is of regular occurrence in the olfactory epithelium and in that of the labyrinth. Mr. de Santi has recently removed a melanotic cancer growing high up on the nasal septum, and the patient so far has no recurrence. The case is an extremely rare one. Mr. Arthur Cheate has informed me that the occurrence of a melanotic growth in the labyrinth is not known to him.

#### CONCLUSION.

Experience incident to the removal of a large number of melanomas is similar to that in connexion with other varieties of new growths. Free and early excision is not followed by recurrence *in situ* except in malignant cases where the disease has already spread widely. Simultaneously with the change from melanoma to melanotic cancer there is a detachment and degeneration of cells producing metastasis which exhibits itself later on.

The general bearing of recent observations suggests the hope that further chemical research may arrive at a means of controlling the disease by therapeutic measures.

## DIFFICULT MIDWIFERY IN GENERAL PRACTICE.

BY

S. GORDON LUKER, M.D., B.Ch., F.R.C.S.,  
M.R.C.P.,

LECTURER ON MIDWIFERY AND DISEASES OF WOMEN, LONDON HOSPITAL.

IN reading a paper and opening a discussion on such a comprehensive subject as difficult labour, I intend to limit myself to certain conditions and varieties of difficult labour which occur most frequently. In some of these the treatment has altered during recent years, and what was the accepted practice twenty years ago is now changed or considerably modified.

I would begin by emphasizing the fact that the importance of the obstetric branch of the art of medicine has of late been recognized in all the teaching schools. Less than twenty years ago the hospital student gleaned a few rudimentary facts from some small manual and proceeded to attend cases on the district with but a sketchy knowledge of the essential principles; the student of the present day attends the lying-in ward of his hospital day and night for a month before being allowed to attend cases on the district; and instead of an optional two months he is obliged to act as clinical clerk in the obstetric department for four months. Thus, by adequate instruction on normal cases and a considerable experience of abnormal cases, he comes to realize two very important things: first, the value of patience and the danger of interference in straightforward cases; and secondly, the importance of correct diagnosis in a difficult case so that the appropriate treatment may be carried out.

What the newly qualified doctor of the present day finds difficult is how to apply his hospital methods to general practice. For whereas in the hospital maternity ward time is no object, this is very far from being the case in private practice, and the doctor is found to be confronted at times with the problem of what is the best thing to do "in the circumstances." Sometimes forceps are applied before the suitable time has really arrived. In others, version has been performed. Sometimes all goes well, but at others the result is disastrous. The only real remedy lies in providing sufficient maternity beds in hospital in all towns for cases of difficult labour. Until such a time arrives I think it is fair to say that most doctors are to be congratulated on the skill and ingenuity displayed in conducting a busy midwifery practice. No doctor with surgical inclinations would dream of starting to remove an appendix in an ordinary bedroom, but there is no doubt that this is safer than many operations of difficult labour. In order to justify this assertion I would state that the mortality due to, and resulting from, childbirth is still very high for a "purely physiological" process, as it is termed.

The death rate per 1,000 births in 1920 was 4.1 (of which 2.25 were directly due to abnormal labour, and 1.87 to puerperal sepsis of which the cause was often difficult labour).

Next, I will digress from the subject of my paper in order to speak about a theme of the greatest importance—namely, the prevention of difficult labour; and herein lies the most important advance in the practice of obstetrics.

#### The Prevention of Difficult Labour.

Ante-natal clinics have been formed and are still being formed all over the country, where the care of expectant mothers is carried on with great zeal. In the ante-natal clinic of to-day the pregnant woman is examined from time to time so as to exclude any possibility of difficult labour arising unforeseen. In noting the important points some such scheme as the following is used:

#### Scheme for Notes.

- Age.
- Date of last menstrual period.
- Expected date of confinement.
- Previous pregnancies or labours, with their character.
- External Measurement: Interspinoous. Intercristal.

\* A paper read before the Dover and Folkestone Branch of the British Medical Association.

reflex slowing of the heart rate owing to stimulation of the depressor nerve endings in the aortic arch through raising of the blood pressure due to the increased flow of blood to the right side, caused by the abdominal effort necessary to sustain the column of mercury.

Certain subjects display a combination of these results as regards arterial pressure readings—namely, a high systolic and a low diastolic pressure: for example, SP 150, DP 60, PP 50. Such individuals are "highly strung" as regards nervous stability and markedly inefficient as regards physical stamina. From the point of view of air work, such subjects present an interesting response to rotary movement; when they are rotated ten times in twenty seconds but the DP falls, and fainting may ensue. In certain individuals who are relatively physically efficient the rotation induces a marked rise of both systolic and diastolic pressures, and such individuals are probably liable to suffer from nausea and vomiting in the air.

The abdominal wall plays an important part in counteracting the influence of gravity in producing abdominal venous congestion in the upright posture, and it is impossible to over-estimate the importance of a good-toned, mobile abdominal wall in maintaining efficient circulation. When the abdominal wall is lax and ineffective the supply of blood to the heart during exercise will be insufficient, owing to the large abdominal pooling of blood, and the heart will therefore, to meet the demands of the body, be obliged to pump a relatively small supply of blood at a quicker rate. Such increased heart rate is frequently regarded as a sign of myocardial insufficiency, whereas in many such cases it is due to an efficient heart making the best use of a poor supply of blood. Such a condition is often found in persons who have returned from the tropics.

The ill effects of gravity are further counteracted by the tonic contraction of the splanchnic arterioles. Information as to the tone of these vessels is afforded by the pulse when the subject rises from the sitting to the standing posture. Generally speaking it may be taken as true that the greater the increase in pulse rate, and the more prolonged the quickened rate, the greater the insufficiency.

Circulatory efficiency may be assessed as follows: (1) A normal steady heart beating about 72 a minute, not unduly increased in rate by exercise and returning quickly to normal steady rate. (2) A pulse pressure of 40-50 mm. Hg associated with a well sustained diastolic pressure (about 80 mm. Hg). (3) Absence of abdominal pooling in the venous reservoir due to the effects of gravity on the circulation owing to poor tone of the abdominal belt of musculature.

Stability of General Nervous Control.—The importance of stability of the circulatory and respiratory centres in the maintenance of physical efficiency has been indicated above. General nervous stability plays a great part as regards bodily endurance. The tests employed in the R.A.F. are considered to be sufficient to reveal the condition of physiological or psychological control. This tremor is evidence of some disordered functional state. Tremors of the eyelids are usually indicative rather of a highly strung disposition or the result of legitimate stress, such as overwork or strain of occupation; tremors of fingers and hands rather of illegitimate stress, such as excessive indulgence in tobacco or alcohol; while tremor of both eyes and fingers generally signifies nervous instability due to a combination of the above causes. As regards the knee-jerk, a so-called brisk or exaggerated response is not in itself necessarily an indication of nervous instability, but a condition not infrequently called "exaggerated knee-jerk," indicated by a convulsive movement of the whole body, indicates loss of general control, and has nothing to do with tendon reflexes. This "exaggerated knee-jerk" is usually associated with a state of anxiety, conscious or subconscious. The tests of standing on one foot with the eyes closed, and of balancing a rod on a flat board, elucidate the condition of "muscle-sense" or "vestibular stability"; failure in

erating stability: 2  
erating temperatur  
erage temperature:

them, therefore, indicates some want of afferent or efferent control. In many instances it is the failure of the control through the medullary centres which predisposes to breakdown of the higher centres.

Our knowledge of the diseases to which man is subject is being added to continually, and in all probability at no period in the history of the human race has that knowledge been so complete as it is at the present time. All diseases and defects must be considered abnormal, and while our knowledge of what may be styled "normal man" does not appear to have increased to the same extent. There are only a few generally accepted standards of normality, in spite of the advantages to be derived from the possession of such standards. No accurate assessment of the degree of any abnormality is possible without a standard of that which is normal. In the past we have been content to express the physical or mental attributes of the individual in such abstract terms as "good," "bad," and "indifferent."

Standards of normality are essential not only in estimating the degree of abnormality from which, as medical men, we may know an individual to be suffering; they are of importance for comparative purposes to those who have the care and upbringing of the rising generation entrusted to them; they should prove of great help in life insurance from an actuarial point of view; and they are indispensable to any scientific selection of recruits for the various arms of the fighting services.

Before proceeding further it will be well, perhaps, to try and define what is meant by "normality," as applied to man. When we speak of an individual having normal physique or normal mental capacity, we infer that the stature, weight, physical proportions, and mental attributes of that individual represent a normal average of the race to which he belongs. Further, it may be desirable to subdivide the races into different classes, in order to obtain a standard of normality for that particular section of the community. It is not possible to lay down standards of normality suitable to all races; a standard suitable for the native races of Central Africa would be quite unsuitable for the assessment of the inhabitants of these isles, and vice versa.

In the past physique has been regarded as one of the most important factors with reference to the selection of recruits for a fighting force, and in ancient warfare involving hand-to-hand fighting there can be no question that the side with the better physique possessed the advantage; but with the advent of long-distance projectiles this advantage has been minimized, whilst at the same time the "fragility" of modern warfare, with its accompanying nervous strain, has focused attention on the importance of psycho-physical and psycho-physiological characters. The soldier nevertheless remains a beast of burden, compelled at times to carry a weight of equipment far in excess of any load he has been accustomed to in civil life, and in addition he may be called upon to undergo fatigue, extremes of temperature, and climatic exposure under the most favourable conditions for contracting disease.

**Abdominal Examination:**

Height of fundus uteri; waist girth.

Lie and presentation of the foetus.

Foetal heart.

Size and situation of the foetal head, and whether it is engaged or can be made to engage in the brim of the pelvis.

**Vaginal Examination:**

Whether there is any abnormality of the soft parts.

Whether the sacral promontory can be felt; if so, the diagonal conjugate must be measured.

Whether the foetal head is engaged.

Whether there is any tumour in the pelvis.

**Examination of the Urine:**

This examination should be made during the seventh month and repeated about the thirty-sixth week, or more often if necessary.

At or soon after the thirty-sixth week it will generally be possible in a normal woman with a normal pelvis to say that labour will be normal.

This examination, carried out as a routine in all cases, is absolutely indispensable in first pregnancies, where special precautions have to be taken to deal with the following abnormalities: contracted pelvis; large foetus; breech presentations; other abnormal presentations.

This brings me to the first cause of difficult labour—namely, the contracted pelvis.

**Contracted Pelvis.**

Extreme degrees of contracted pelvis calling for Caesarean section are rare. Slight degrees of pelvic contraction are common and perhaps one of the commonest causes of difficult labour. For if the contraction be slight, examination during the last week or two of pregnancy may reveal nothing obviously wrong; when labour starts, however, the head fails to descend through the brim of the pelvis and early rupture of the membranes may occur. In such cases it is most important to make preparation for a long labour, and to make a firm resolution not to apply forceps until it is certain that the woman is unable to deliver herself unaided. In the early stages it is important to empty the bowels by castor oil and an enema, and to keep the bladder emptied, and maintain the patient's strength by light nourishment at frequent intervals. The keynote of the treatment is to allow time for the head to mould. The patient generally requires rest and sleep during such a labour, and this is best ensured by giving an injection of half a cubic centimetre of omnopon with scopolamine, repeated in an hour if necessary. There is no drug or combination of drugs so valuable, in my opinion, owing to its certainty of action. Forceps should be withheld until the following indications are present:

1. Foetal distress.
2. The head is sufficiently moulded and low down in the pelvis to allow a reasonable chance of delivery.
3. Maternal distress.
4. Commencing oedema of the vulva or vaginal orifice.

Cases in which these rules are disregarded are far from uncommon in the crowded districts of London; the patient, generally a primigravida, is sent up to hospital by her doctor because he has failed to deliver her with forceps. On examination she is found to be suffering from shock, but the os uteri is not completely dilated. An injection of omnopon and scopolamine is given and after a few hours' rest or sleep spontaneous delivery not uncommonly occurs.

**Large Size of the Foetus and Foetal Head.**

This is as common or commoner than contracted pelvis as a cause of difficult labour, and results in many cases from post-maturity. I have recently been much impressed with the frequency and importance of prolonged pregnancy. The normal period of gestation is 280 days, or forty weeks from the first day of the last menstrual period, but it is not infrequently prolonged a week or two. The foetus thus becomes unduly large and its head abnormally hard, so that when labour does come on it is difficult and prolonged, there is tearing of the maternal soft parts, and risk of injury to, or death of, the infant. Such difficulty can be prevented by terminating labour at the appointed date. This can be brought about by a simple scheme of treatment, provided that the details are carried out with care and precision.

The scheme, which may be called the "Intensive Method of Induction," is as follows:

On the expected date of confinement, first thing in the morning, say 7 o'clock, one ounce of castor oil is given; the result is best if it is given emulsified in a cup of very hot milk. After this a light breakfast is allowed. One hour later a hot bath is given for about fifteen minutes, the patient being immersed up to her waist. After this a tight binder is applied. One hour later a copious enema of soap and water is given. One hour later 10 grains of quinine sulphate are given with a hot drink. If labour does not start within two hours, 10 grains more of quinine sulphate are given with a hot drink, and this may be repeated again two hours later.

During the past six months this method has given uniformly good results in the obstetric ward of the London Hospital, and in other private cases directly and indirectly under my care, not only for women at term, but also as a means of inducing premature labour. In the event of the treatment being unsuccessful in its object it may be repeated in forty-eight hours and supplemented by two or three small injections of pituitrin. If this treatment is unsuccessful a second time, labour may be brought on by the introduction of bougies. In addition to the cases where pregnancy is prolonged, there are those in which it is advisable to bring on labour a week or two before full term because the foetal head has not engaged and seems to be getting large. There are also the cases of pelvic contraction in which premature induction of labour has to be carried out about four to five weeks before term.

**Breech Presentation.**

Next, I would like to mention the difficulties resulting from breech labour. These include primary and secondary uterine inertia, prolonged labour, and extension of arms, legs, and head. There is generally no real risk to the mother except that of a torn perineum, but there is a definite risk to the foetus especially in first labours, in which the mortality is certainly over 10 per cent. It is, therefore, important to prevent breech labour in primigravidae; this can be done by performing external version before labour starts, and converting the breech into a vertex. The most suitable time at which this can be done is the thirty-fifth week.

**Ante-partum Haemorrhage.**

Of recent years the treatment of ante-partum haemorrhage has followed much more conservative lines than formerly. First, it is important to find out whether the bleeding is accidental or whether it results from placenta praevia. If the placenta cannot be felt by the finger passed through the cervical canal into the uterus the case should be treated as one of accidental haemorrhage and an expectant policy adopted for at least twenty-four hours. The patient is put to bed—in a hospital or nursing home if possible—and a hypodermic injection of morphine is given. Plenty of fluid may be taken by the mouth and in severe cases rectal saline may be given. The essentials are rest and warmth, so that the patient may recover from shock and the tone of the uterus may be restored. In many cases labour starts within twenty-four hours and spontaneous delivery takes place. If labour does not come on and fresh bleeding occurs, the best treatment is to rupture the membranes or to give an injection of pituitary extract. Either method will generally be followed by the onset of labour within a few hours. The advantage of rupture of the membranes is that labour is pretty certain to come on without delay; the disadvantage of pituitary extract is that its effect may wear off after a few hours and the uterus may again become atonic. If rupture of the membranes is followed by pains which are weak and infrequent there is no objection to giving an injection of pituitrin as well.

The same method of treatment may be followed in some cases of placenta praevia, but more often the bleeding is severe and recurrent, if not continuous, so that steps must be taken to stop the bleeding by inserting a Champetier de Ribes's bag or by performing version and bringing down a leg. But here again there are many cases which do very well if the membranes are ruptured and a tight binder applied. The treatment of placenta praevia by

The average stature of the general population, according to Sir Arthur Keith, is approximately 67½ inches, and according to the same authority some 50 per cent. of the population have a stature ranging between 65½ and 69½ inches. Unfortunately we have no available statistics for our own forces of the relationship between stature and disease, but some exceedingly interesting and instructive figures showing the proportionate measurements of recruits and soldiers in the late war who suffered from special diseases have been prepared by the United States Army Medical Service<sup>1</sup> and have an important bearing on this

[illegible]

physical characteristics, which when combined in the proper proportion give us a picture of the physically normal man. This question has been discussed fully in a paper I had the privilege of reading before the Royal Society of Medicine.<sup>2</sup> Briefly, I think we may state that the generally accepted opinion at the present time is that in the normal man all proportions of his body have a distinct relation to one another, and that the old method of using age as the factor for expressing the relationship was fundamentally wrong. On the other hand, if we use some physical factor—as, for instance, stature or trunk height—we shall find that in the normal individual all

\_\_\_\_\_

Let us see what bearing the foregoing remarks have with regard to the fixing of the physical standard for the selection of recruits. I do not think we shall be far wrong if we assume that the average normal man from the mass population may vary in stature from 65 to 70 inches. The average height of all recruits at the Central London Recruiting Depot during the past three years has been 66.2 inches. If we could select all our recruits from youths having

[illegible]

It may be asked, How is the question of physical normality affected by age? The answer is that during the actively growing period—that is, up to 21 years—the question of age need not be considered. The physically normal youth of 70 inches should weigh approximately 140 lb., and have a chest measurement at rest of some 33 inches. In no matter what is his age—17, 18, 19, or 20 years. A table of physical equivalents (see p. 325) showing

the normal in regard to their weight and such conditions of defective physical development sufficient to brand them as "unfit," but a fair proportion may present no other

Caesarean section is but rarely indicated, and should be reserved for special cases, as follows: (1) When the patient is a primigravida with a rigid undilated os and central placenta praevia, and the foetus is known to be alive. (2) When the patient is a multipara who has lost a lot of blood and can ill afford to lose any more. If I might emphasize one point in the treatment of ante-partum haemorrhage it is that the condition is one in which the advantages of treatment in a hospital or nursing home are very great.

#### Version.

I have already mentioned the value of external version during the later weeks of pregnancy to convert a breech presentation into a vertex. In such cases it may be easy, but an anaesthetic is often required. Version is also the correct treatment for a transverse lie, and in certain cases of placenta praevia. Version should never be performed to effect delivery when the presentation is a vertex and forceps have failed to effect delivery, for in such a case there is great danger of rupturing the uterus. This danger is very real in a transverse lie if version is attempted late in labour. Whenever the uterus is becoming irritable, and the pains are strong and frequent and cannot be completely abolished by anaesthesia, it is unsafe to attempt version. In such a case the foetus is nearly always dead, and its life need not be considered as in any way comparable with the mother's safety. Delivery should therefore be effected after perforation of the foetal head in a vertex presentation, or after decapitation for a transverse lie.

In placenta praevia and in accidental haemorrhage the uterine wall may be weak in places and easily ruptured if any force is used in performing version. Version should not be persevered with if reasonable attempts are unsuccessful, as the failure may be due to insufficient liquor amnii.

#### Post-partum Haemorrhage.

As in ante-partum haemorrhage, the cause of post-partum haemorrhage is generally (1) uterine exhaustion or lack of tone; (2) some placenta or membranes left behind in the uterus. In my opinion a most important predisposing cause of these two conditions is chloroform when given in fair quantity for a prolonged period, especially if pushed to a sufficient extent to allow the application of instruments. There is nothing which abolishes uterine contractions so quickly and effectually as chloroform, or, to a lesser extent, ether; and if the anaesthetic is given for any length of time there is likely to be difficulty in the third stage owing to deficient uterine contractions and post-partum haemorrhage will occur.

Post-partum haemorrhage is also likely to follow the overdistension of the uterus by twin pregnancy or hydramnios. In such cases, therefore, it is very important to keep very careful watch over the uterus for at least an hour after the delivery of the infant, and to have preparations in hand for a hot vaginal and intrauterine douche. If haemorrhage occurs after the expulsion of the placenta a hypodermic injection of pituitary extract should be given at once, and should be followed by a hypodermic injection of ergot.

#### Caesarean Section.

The comparative ease and safety with which Caesarean section can be performed has led to a considerable increase in the number of the operations. The scope of the operation has been widened to include not only the extreme cases of contracted pelvis, but also cases of pelvic contraction of a minor degree, of malpresentations, of eclampsia, of placenta praevia, and of accidental haemorrhage. The increased frequency with which the operation has been performed during the last few years has been accompanied by, first, an increased maternal mortality, and secondly, a considerable number of unfavourable post-operative sequelae of which the most serious is rupture of the uterine scar in a subsequent pregnancy. The result is that the pendulum has begun to swing in the opposite direction, and the number of cases of Caesarean section, in the London hospitals at any rate, has dropped considerably. The indications for Caesarean section should

certainly be as definite as for any other major operation. Before Caesarean section is undertaken the following points should be ascertained: (1) that the foetus is alive; (2) that the foetus has no reasonable chance of delivery *per vias naturales*; (3) that the labour is not far advanced; (4) that there is no undue risk to the mother. The great risk in the operation is sepsis from the uterus, resulting in death of the mother from peritonitis or septicaemia, or breaking down of the abdominal or uterine wound. If any sepsis be present the uterine wound will not heal well so as to leave a good scar. Weakness of the scar may also result from inefficient suture of the uterine wound. There is no operation in which it is more important to have favourable conditions for the carrying out of a perfect aseptic technique. The risk of a weak scar has of recent years been overcome by making the incision into the uterus through the lower uterine segment after pushing down the bladder. The objection to this is that the operation is more difficult, and if the child is large it may be difficult to extract. The incision has much to recommend it, and I consider it a marked advance on the old incision. Caesarean section in cases of eclampsia has a high mortality, among hospital patients at any rate, and is performed less frequently than formerly. Caesarean section in cases of central placenta praevia or severe accidental haemorrhage is, in my opinion, a good method of treatment in picked cases.

#### Unreduced Occipito-posterior Position.

The difficulties likely to arise in connexion with an occipito-posterior position result from uterine inertia, prolonged labour, and the application of forceps. Following these there may be a torn perineum, torn cervix, or injury to the bladder, and permanent weakness of the pelvic floor resulting from difficult forceps delivery. There is also a possibility of rupture of the uterus during forceps or manipulations. The correct treatment consists in making sure of the diagnosis when the condition is suspected, and promoting flexion of the foetal head during the first stage, by postural. If the occiput does not rotate after a reasonable time in the second stage an anaesthetic should be given and the head, with the body of the foetus, should be rotated. If reduction cannot be performed and the head is well down, tentative and judicious trial of axis traction forceps may be made. If the head does not descend with gentle traction, perforation of the foetal head should be performed.

After the paper there was a discussion, and questions were asked by many members present. In reply Mr. Luker pointed out that he did not think that any harm resulted from giving drops of chloroform during the latter part of the second stage, but he wished to emphasize the danger, in his opinion, of large quantities for any length of time.

### ACUTE LUMBAGO TREATED BY THE INJECTION OF QUININE AND UREA.

BY

H. S. SOUTTAR, M.Ch.Oxon., F.R.C.S.Eng.,

SURGEON (WITH CHARGE OF OUT-PATIENTS), LONDON HOSPITAL.

Of common minor ailments there is none which may be more completely paralysing than acute lumbago. In an instant an individual in the full vigour of health may find himself unable to make the slightest movement of the trunk without the most exquisite pain, and he may remain confined to bed for weeks as an absolute cripple. Even in the slightest cases, though the acute symptoms may pass off in a few days, it will be ten days at least before he can stoop with freedom and comfort. In severe cases the slightest movement, or even a sudden noise, may induce a spasm of pain, with a violent contraction of the lumbar muscles, a reflex attempt at protective fixation. The contraction may last for several seconds, and only slowly and cautiously will the patient allow the muscles to relax.

An attack is often brought on by a chill following exertion, such as may occur from sitting in clothes damp from perspiration. An attempted movement produces a spasm

of pain, and after that free movement is impossible. The pathological basis is very obscure and probably involves a number of different factors. The circulation in the muscles, diminished by cold, is unable to remove the waste products resulting from recent activity. Probably the muscle responds to stimuli by an irregular spasm, and a few of its fibres are torn from their origin. This conception would at least explain the fact that it is almost always at a point of attachment that tenderness is most marked.

Though the sudden onset is strongly suggestive of a traumatic origin there is usually a slight but definite constitutional disturbance, and it seems probable that the trauma would be ineffective in the absence of some error in general metabolism, perhaps due to a low grade of infection. But the local symptoms are so severe as entirely to absorb the patient's attention. A close examination will indeed show that the source of these symptoms is even more narrowly localized than the patient imagines, and that the pain spreads from a very small focus characterized by exquisite tenderness to deep pressure. This focus may be situated anywhere in the lumbar muscles, and in addition to its excessive sensitiveness may be marked by a slight local swelling, with an oedema which pits on pressure.

The precise localization of the focus of pain naturally suggests some local form of treatment, and a large number of methods have been recommended. Radiant heat, dry cupping, heavy massage, the insertion of long needles, and the actual cautery, all have their advocates, but the more lenient methods are tedious, whilst the more drastic are somewhat oriental. It occurred to me that the injection of a local anaesthetic would be a rational method to employ, and could at least do no harm. I was scarcely prepared, however, for the instantaneous cures which I have observed, and still less for their permanence.

The anaesthetic I chose was quinine and urea hydrochloride in 1 per cent. solution, and I selected it because of the length of time, up to several days, for which the anaesthesia may last. I thought at first that the action might be purely mechanical and I tried normal saline solution, but the effect proved to be only transitory. 5 c.cm. of the solution is injected through a long fine needle into the centre of the tender spot; within ten minutes the acute pain has entirely disappeared and the patient can move freely; a sense of stiffness remains, and a curious feature is that the patient may complain of a general malaise. It has seemed to me probable that some constitutional disturbance is a regular feature of the condition, but that it is masked by the severity of the local pain.

The following cases illustrate clearly the method employed and the results.

A lady, aged 45, was suddenly seized with severe pain in the right loin. The pain came in spasms so severe that whilst they lasted the right leg appeared to be paralysed and the possibility of a lesion of the lumbar roots was even considered. She lay in bed unable to move, the slightest attempt at movement provoking an attack of pain. Massage, radiant heat, and moist heat only gave partial and temporary relief. Below the iliac crest and just external to the right sacro-iliac joint was an area about the size of a florin, slightly boggy to pressure, and exquisitely tender. Into this area a hypodermic needle was passed till it reached the bone, and 5 c.cm. of a 1 per cent. solution of quinine and urea hydrochloride was injected. Ten minutes later the patient found that she could move without producing a spasm, and in two hours she could get up and walk. There were no further spasms, and beyond a feeling of stiffness which lasted for ten days she declared herself cured.

A lady, aged 52, passing through London was seized with violent pain in the lower right lumbar region on attempting to rise from bed in the morning. She had had a previous attack of lumbago which confined her to bed for three weeks (under the care of an osteopath who informed her that she had dislocated her sacro-iliac joint!). There was a tender spot just external to the right sacro-iliac joint, and as the case was one of moderate severity I tried the injection of 5 c.cm. of normal saline solution. Marked relief followed, but only lasted a few hours. An injection of quinine was, however, followed by complete relief, and two days later she was able to travel. A month later she wrote to tell me that she had had no further pain and was perfectly well.

It seems to me that a method at once so simple and so safe ought to be generally known and that it must have extensive applications. I have little doubt that it would be equally effective in those similar cases of torticollis and

pleurodynia where a localized tender spot is always a marked feature.

## THE EFFECT OF PARATHYROID ON THE BLOOD SUGAR CURVE AFTER INSULIN.

BY

W. DEVEREUX FORREST, M.D.,

HONORARY MEDICAL REGISTRAR, ROYAL VICTORIA INFIRMARY,  
NEWCASTLE-ON-TYNE.

WINTER AND SMITH have recently reported<sup>1</sup> that when insulin and parathyroid are injected simultaneously into rabbits, convulsions (due to reduction of the amount of sugar in the blood) ensue in a much shorter period and with a much smaller dose of insulin (one-third to one-fourth of the normal dose). I applied these results to the human subject, and found that parathyroid was almost, if not quite, as efficacious when given by mouth, and in the cases reported below this method was used. The procedure in all the cases was the same. The patient was not allowed any food beyond clear soup for five hours before injection. The parathyroid and insulin were administered, and the first blood taken within five minutes, and blood-sugar estimations were carried out hourly from that time to the end of the observation period. No food was given until after the last estimation.

## CASE I.

H. S., male, aged 36. Diabetes diagnosed two years ago. He was treated on a modified Allen diet, but was careless, and persistently overstepped it by small amounts. He had got worse of late, and developed marked ketonuria in July, without any alteration of diet. Twenty units of A.B. insulin given alone. Blood sugar: 0.310, 0.265, 0.227, 0.162, 0.155, 0.187, and 0.234 per cent.  
Twenty units of A.B. insulin with four 1/10 grain parathyroid tablets. Blood sugar: 0.329, 0.257, 0.196, 0.141, 0.118, 0.102, 0.136, and 0.169 per cent.

## CASE II.

J. A., male, aged 45. First symptoms in February, 1922. Was thirsty, and lost over 2 st. in weight. Was treated on old lines with codaine, and restriction of bread. Improved for a few months, but lost ground again towards the end of the year. Admitted to the infirmary in January, and was given three doses of insulin, and put on to the Allen dietary. Was a bad patient and did not adhere to his diet. Returned again in September, and was treated with insulin. Twenty units of insulin given alone. Blood sugar: 0.312, 0.292, 0.256, 0.201, 0.216, 0.238, and 0.277 per cent.  
Twenty units of insulin with twelve 1/10 grain tablets of parathyroid. Blood sugar: 0.329, 0.236, 0.195, 0.149, 0.125, 0.091, and 0.081 per cent.

## CASE III.

H. R., female, aged 55. Chronic case. Had had glycosuria for four and a half years to her knowledge. Had been thirsty occasionally, but main complaint was pruritus. Present weight 13 st. 1 lb. Had been 17 st. The blood sugar curve was definitely diabetic. Twenty units insulin given alone. Blood sugar: 0.362 per cent., missing, 0.214, 0.156, 0.172, and 0.224 per cent.  
Twenty units insulin with ten parathyroid tablets. Blood sugar: 0.339, 0.246, 0.182, 0.125, 0.107, 0.091, 0.088, and 0.122 per cent.

## CASE IV.

L. S., male, aged 23. In January this year he showed typical symptoms. He was treated by a modification of the Allen diet, and improved greatly. In July he felt worse again, and it was found that his tolerance had dropped from 95 grams carbohydrate to 60. He was readmitted, and given insulin, with marked benefit and slight increase in weight. Unfortunately, being worried about the necessary expense, he dropped the insulin, and became worse again. Fifteen units insulin given alone. Blood sugar: 0.284, 0.243, 0.216, 0.153, 0.167, and 0.202 per cent.  
Fifteen units insulin with six parathyroid tablets. Blood sugar: 0.322, 0.246, 0.191, 0.153, 0.121, 0.104, 0.118, and 0.143 per cent.

## CASE V.

M. M. W., female, aged 26. Diabetes was diagnosed at Christmas, 1922, but she had symptoms for a considerable time previously. Refused to come into hospital until quite recently, and had had practically no treatment hitherto. Fifteen units insulin given alone. Blood sugar: 0.410, 0.326, 0.229, 0.277, 0.229, 0.242, and 0.283 per cent.

whom a nervous instability is either inherent or the result of incipient disability, and it is with regard to these cases that every effort should be made to eliminate them from the fighting forces. The most suitable place for this to be done is at the training depot, where, by watching the behaviour characteristic of the recruits in conjunction with their physiological response to improved environment, and training, and their ability to receive instruction, a very useful guide as to the recruits' psychology may be obtained, but at the same time much may be done at the recruiting depot to eliminate those who are mentally deficient or nervously unstable.

The mental tests devised by Binet provide a very useful basis for standardizing the degree of mental efficiency necessary for a recruit on enlistment, and also for classifying recruits according to their mental capacity; it is not possible, however, to adopt a classification of this nature in a voluntary army, but it is quite feasible to introduce a minimum standard of mental capacity below which no recruit will be enlisted. Such a mental test should aim at arriving at the normal mental capacity of the general population, which, in all probability, is not more than a 12- to 14-year mental age, according to the Binet-Simon method. A list of mental tests suitable for recruiting purposes is given in an appendix. These have been selected mostly from *The Measurement of Intelligence*, by Terman, and have proved to be of some help in actual practice at the Central London Recruiting Depot.

The objection to mental tests is that the results are of little value in inexperienced hands, and should be carried out, if possible, by psychological experts. Recruits who are liable to break down from war neurosis are frequently suffering from some incipient disease, also they may present signs of some physiological derangement, such as exaggerated reflexes, functional heart trouble, etc., which indicates the importance of the standards of physiological normality mentioned above.

#### APPENDIX.

##### MENTAL TESTS FOR RECRUITS.

##### Test No. 1.—Ball and Field Test.

Procedure: Let us suppose that your cricket ball has been lost in this round field. You have no idea what part of the field it is in. You don't know what direction it came from, how it got there, or with what force it came. All you know is that the ball is lost somewhere in the field. Now take this pencil and mark out a path to show me how you would hunt for the ball so as to be sure not to miss it. Begin at the gate and show me what path you would take.

Nos. 1 to 5 are samples of "superior plans," satisfactory at 12 years.

(For a pass, recruit must equal 1 to 5.)

##### Test No. 2.

Repeat 5 digits backwards. (1 of 3. Read 1 per second.)

3-1-8-7-9..... 6-9-1-8-2..... 5-2-9-6-1.....  
 Procedure: Listen carefully. I am going to read some numbers to you, but I want you to say them backwards. For example,

if I should say 1, 2, 3 you would say 3, 2, 1. Do you understand? Ready, now! Listen carefully, and be sure to say the numbers backwards.

(Marking: One out of 3 passes.)

Test No. 3.—Clock Test.

Clock. (2 of 3. Error must not exceed 3 or 4 minutes.)

Time required	6.22
Time required	8.10
Time required	2.46

Procedure: Suppose it is 6.22 o'clock—that is, 22 minutes after 6. Can you see in your mind where the large hand would be, and where the small hand would be?

Now suppose the two hands to change places, so that the large hand takes the place where the small hand was, and the small hand takes the place where the large hand was. What time would it be then?

Scoring: Two or three problems must be solved within following range of accuracy: 4.30-4.35, 1.40-1.45, 9.10-9.15.

Test No. 4.

Procedure: Listen carefully. I want you to imagine that you are with a companion, drifting in an open boat, on sea. When you started your journey you had two buckets full of fresh water.

The first day you drank the water contained in one bucket. The next day your companion set fire to his clothes whilst lighting a cigarette. What are you going to do?

(Tells if he throws the bucket of fresh water over his companion. Passes if he pushes him into the sea. Will marks if he fills empty bucket with sea water and uses that.)

Test No. 5.

If a lad's wage is 20s. a week and he spends 15s. a week, how long will it take him to save 300s.?

If 2 pencils cost 5 pence, how many pencils can you buy for 50 pence?

At 15 pence a yard, how much will 7 feet of cloth cost? (Score: Should pass 2 out of 3, allowing a minute to each problem.)

Test No. 6.

Repeat 28 syllables. (1 of 2 absolutely correct.)

a. Walter likes very much to go on visits to his grand-mother, because she always tells him many funny stories.

b. Yesterday I saw a pretty little dog in the street. It had curly brown hair, short legs, and a long tail.

Procedure: I am going to read a sentence to you. Listen carefully, as I want you to repeat it to me without a single change of any sort.

(Marking: Pass if one sentence is repeated without a single error.)

Group Captain MARTIN FRANK stated that all precautions possible were taken to put candidates for the Royal Air Force at their ease and to distract their attention while the pulse rate was taken. The history of athletic prowess was important in a candidate.

Lieut.-Colonel N. J. CHAWORTH mentioned asked for information on the following points: (1) Could a standard by arrived at to eliminate the number of recruits discharged under six months' service as unfit owing to middle-ear diseases? In spite of otoscopic examination of all recruits on enlistment discharges for middle-ear disease continued to head the list. (2) The advisability of simple mental tests on enlistment. He remarked on the usefulness of having a record of the recruit's mentality on enlistment to prevent subsequent discharges as "mental inefficient," as the recruit's mental attitude towards solidifying might alter.

Lieut.-Colonel W. SATSWORTH-SMITH agreed that marked deviations from the average of stature, either above or below, were disadvantageous to the individual. With reference to hearing tests, the only satisfactory watch was a stop-watch which could be started and stopped without audible click. The recognized standard instrument for ticking sounds was the aneroid; this should be heard at a distance of fifteen feet in an ordinary room.

#### DISCUSSION.

Fifteen units insulin with ten tablets of parathyroid. Blood sugar: 0.356, 0.258, 0.231, 0.177, 0.143, 0.119, and 0.106 per cent., and after a four hours' interval, during which she was given 20 grams of carbohydrate, 0.259 per cent.

From the above cases it is evident that parathyroid extract exerts a very definite action on the blood-sugar curve after exhibition of insulin. Whether this will be of any importance as regards treatment is not yet clear. Parathyroid alone does not appear to have any action on the blood sugar; such changes as have been noticed could easily be explained as the result of starvation.

Further investigations are in progress to ascertain the therapeutic possibilities of the combination.

I am indebted to Professor W. E. Hume for Case ii.

British Medical Association.

PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, 1923.

SECTION OF NAVAL AND MILITARY HYGIENE.

Surgeon Rear-Admiral Sir PERCY WILLIAM BASSETT-SMITH, K.C.B., C.M.G., F.R.C.S., R.N.(ret.), President.

RECENT CHANGES IN FRACTURE TREATMENT.

BY

MAJOR M. SINCLAIR, C.M.G., R.A.M.C.,  
Royal Victoria Hospital, Netley.

(With Special Plate.)

I HOPE you will forgive me if I say at the outset that this extremely important branch of orthopaedic surgery has never, in my opinion, received adequate attention in our medical schools. The unsatisfactory results of the treatment of fractures which consequently occurred in practice once prompted a celebrated surgeon to declare to his class: "Bones are not filled with marrow, but with base ingratitude."

When I was a student I remember the late Professor Chiene of Edinburgh advising us, in one of his lectures, to pass along our fractures to rivals practising on the opposite side of the street. In this sadly humorous manner our distinguished teachers warned us, at the earliest possible moment, that fractures would often prove difficult matters to deal with, and that, even in their skilful hands, the results were not always satisfactory. They were, of course, speaking of the treatment of fractures on what we now call "the old lines."

The very commencement of the twentieth century, however, marked an epoch in the history of fractures, for Professor Roentgen's discovery of x rays in 1895 and its application to the study we are now discussing wrought a wonderful change in our methods of treatment. X rays enable the surgeon to see the actual condition of the fractured bone, and the radiograph is to the orthopaedic surgeon what the ophthalmoscope is to the ophthalmologist and the cystoscope to the urologist. By its correct application he gains information as to the true state of affairs in the condition with which he is dealing, analogous, in diagnostic value, to the exploratory laparotomy of the abdominal surgeon. Still more recently the experiences of the war subjected the accepted modes of treatment to a supremely severe test, exposed their weaknesses, and forced us to evolve new methods as well as improve the old.

Surgical specialists, and others who have taken a special interest in fractures, work under ideal conditions for obtaining the best results, for the former—by holding hospital appointments—and the latter—by private enterprise—are in possession of the essential first-class x-ray equipment and a sufficiently varied selection of splints to assist them. To these the remarks I am about to make do not apply. They chiefly concern the practitioner who

is not conveniently near an up-to-date x-ray apparatus and who lacks a free choice of splints.

Without good x-ray plates or films, however, it is impossible to be sure of obtaining the best results, because a great variety of pathological details may be learnt from a careful study of them, for instance:

1. The presence of a fracture.
2. Its variety and the position of the fragments.
3. A coexisting dislocation of or other injury to a joint.
4. The presence and situation of gas gangrene and of air in the soft parts.
5. The formation and character of callus and the solidity or otherwise of new bone formed.

The condition should be studied from the original films or plates and, preferably, when dry. In a print most of the minute details will be less apparent. The surgeon in charge of the case should himself examine the plates first and diagnose the pathological conditions existing. He may then consult an expert radiologist and see how far their readings coincide. The surgeon who first reads the radiographer's report and then studies the photograph is less likely to acquire the power to perceive accurately the details of abnormalities present.

I would like to say a few words about the method of taking x-ray photographs.

1. Antero-posterior and lateral views should always be taken whenever possible, and stereoscopic pictures should only be relied upon in those situations which are inaccessible from two planes—for example, where the limbs join the trunk.

2. If a fractured limb be properly splinted, either externally by the approved method, or internally by plating, it can be x-rayed without the slightest alteration taking place in the position of the fragments. If the proceeding causes the patient any pain it is evidence of inefficient splinting.

3. In operation cases no more dressing than is consistent with aseptic safety should be in the neighbourhood of the injury at the time it is photographed, as the more material the rays have to penetrate the less clear the detail of the picture will be. On this account the sectional dressings are very suitable as, by their use, a minimal amount of dressing is placed between the limb and the supporting flannel bands.

4. When the limb is x-rayed it is also advisable to replace the metal clips which secure the supporting flannel bands by sterile safety-pins, otherwise the shadow thrown by the clips in the lateral view may obscure important features of the picture.

5. By noting the positions of these safety-pins and by placing some parallel to and others at right angles to the side bars of the splint it is possible to localize on the surface of the limb the position of the particular displacement, foreign body, or fragment of bone, information which will help considerably in deciding how to deal with it.

6. Whenever possible the photograph should include a view of one or more standard bony features, such as the trochanters, patella, etc.

7. The most convenient and economical size of photographic plate for the long bones of the lower limb is one measuring 15 by  $\frac{7}{8}$  inches.

8. In the early stages of the treatment of a fractured limb it is essential to have a mobile x-ray plant which is capable of taking photographs with the patient in his bed and without interfering in any way with the extensions.

If such a mobile plant were available, and placed at the service of any practitioner who required it, in my opinion it would be a great advantage to the patient and profession.

THOMAS'S SPLINT.

Of all the forms of fracture-treatment apparatus which were called upon to stand the supreme test of the great war, it is the universal opinion of the surgeons who went through that ordeal that Thomas's splint alone fulfilled all requirements. In the earlier stages there were many of our profession who had no recollection of ever having seen a Thomas's splint used in the treatment of a fracture, although, it should be noted, these did not include any who had studied under the teaching of Sir Robert Jones.

Professors of surgery to-day cannot say enough in praise of the incomparable advantages of Thomas's splint over

# AEROPLANE ACCIDENTS.

H. GRAHAM ANDERSON, M.B.E., M.D., Glas., Ch.B.,  
F.R.C.S., Edin.,  
Surgical Consultant, Royal Air Force Medical Service; Surgeon  
to St. Mark's Hospital.

## [Abstract.]

The points to be considered in classifying aeroplane accidents are, first, the causes; secondly, the type or in which part of the flight the cause was initiated; and lastly, the actual damaging factor.

## Causes of Aeroplane Accidents.

These may be considered under the following headings:

- (1) Defect in the aeroplane.
- (2) Error of judgement in flying.
- (3) Loss of head.
- (4) Brain fatigue.
- (5) Fear.
- (6) Physical illness.
- (7) Unavoidable causes.

(1) This cause amounts to mechanical failure of some part of the aeroplane, and can be subdivided into (a) breakage in the air, and (b) engine failure. If the engine fails in the air a forced landing is compulsory, but given a fair height—2,000 feet or more—the pilot can usually select a good landing place.

One of the commonest examples of aeroplane accidents is engine trouble just after leaving the ground, and in trying to turn back the pilot loses flying speed and the aeroplane falls to the ground.

(2) Error of judgement in flying is the commonest cause of

aeroplane accidents, and of the many examples of this, perhaps the commonest is when on landing the pupil misjudges his angle, usually overrunning and wrecking the machine. It is difficult to estimate and account for these errors of judgement. In some cases the error may be due to insufficient instruction, and in other cases it may be found on examination that the pupil's standard of vision is below normal; but, on the other hand, the pupil may be physically fit, have normal vision and good balancing power, and in the latter cases it may be a case of delayed reaction times.

(3) Loss of head occurs fairly frequently and accounts for a considerable number of accidents. The pupil in his new occupation of flying is at high tension, and under the sudden strain of an emergency his power to reason and act synchronously may momentarily lapse, and there is seldom time to correct the error made.

(4) In contradistinction to loss of head the pupil in brain fatigue reaches the stage where he has neither the power to reason, decide, or act; a state of mental inertia supervenes. This is due to repeated stimuli received by his brain in rapid succession in his flight—he feels alone, and that he cannot manage to control the aeroplane; he feels helpless, and in a stupor awaits events and takes little part in the aeroplane's control. As a rule, if it occurs, the pupil, even if he should escape injury, soon gives up flying; he is not of a temperament suitable for flying.

(5) Fear, at least in a degree sufficient to disturb flying, is rarely experienced in the air on the first few solo flights, the pupil being far too much occupied and concentrated on details of flying and watching the various instruments.

(6) At an air station medical inspection of the pilots and pupils at regular intervals reveals any organic disease that might lead to loss of consciousness in the air. Flying on an empty stomach may cause faintness, and as in schools flying commences at dawn all pupils are first provided with a good meal, while on long flights pilots are provided with tabloid forms of nourishment.

(7) From time to time unavoidable causes of accidents arise. The terrain in certain areas may be unsuitable and conceal obstacles, while in some aeroplanes the view of the ground in certain positions may be limited.

## The Nature of the Injuries Received.

Surgical work in connection with aviation in general differs but little from that in military and civil life. The difference is mainly one of degree, in that one is mostly called upon to deal with the results of high velocity accidents associated with falls at varying angles and from various heights. Burns are among the most severe forms of injury. The cold at high altitude is extreme, and aided by the rapid transit through the air is apt to cause frost-bite easily. In a large proportion of aeroplane accidents the occupants receive injuries to the face, owing to the impact throwing their heads forward. Fractures of both bones of the leg and fractures involving the ankle-joint are very common.

The sick bay or dressing station should be in full view of the aeroplane, with a look-out man supplied with field glasses always on duty during flying hours. Immediately a crash or forced landing occurs the look-out man telephones to the sick bay, notifying the receipt of the exact site of the occurrence, and proceeds with a stretcher to the accident. With the stretcher is taken an emergency tool-case, which includes crowbars, wire cutters, saw, fire extinguisher, etc. The steward dispatches the ambulance with which two sick-birth attendants go, and with them is a bag containing morphine, hypodermic syringes, chloroform, brandy, first aid and picnic acid dressings, etc. If the injured person is conscious and in much pain morphine should be injected, and the patient conveyed quickly to the dressing station, where his injuries should be examined and treated; chloroform may have to be given, as it acts more quickly than morphine.

## First Aid at an Air Station.

The sick bay or dressing station should be in full view of the aeroplane, with a look-out man supplied with field glasses always on duty during flying hours. Immediately a crash or forced landing occurs the look-out man telephones to the sick bay, notifying the receipt of the exact site of the occurrence, and proceeds with a stretcher to the accident. With the stretcher is taken an emergency tool-case, which includes crowbars, wire cutters, saw, fire extinguisher, etc. The steward dispatches the ambulance with which two sick-birth attendants go, and with them is a bag containing morphine, hypodermic syringes, chloroform, brandy, first aid and picnic acid dressings, etc. If the injured person is conscious and in much pain morphine should be injected, and the patient conveyed quickly to the dressing station, where his injuries should be examined and treated; chloroform may have to be given, as it acts more quickly than morphine.

## Safety Belts, Helmets, and Goggles.

With regard to the use of safety belts endless discussion has taken place among aviators. My own opinion is that before leaving the ground all aviators should see that their safety belts are fastened and should be familiar with the method of their quick release. The belts should never be undone in the air, but a difficult question arises whether to release the belt near the end of a glide before landing. Safety helmets are of undoubted value in school work and prevent scalp wounds and the side flaps protect the ears from injury. Most aviators wear goggles, but there are still some who prefer to fly without them. I certainly think that goggles should always be worn; there is no doubt that flying without goggles is apt to set up a spasm in the eyes.

The term "type of accidents" has been suggested to describe the part of the flight in which the cause of the accident was initiated. A flight may be divided arbitrarily into three parts: first, the getting off the ground and into the air; second, in the air with the various turns, figures of eight, spirals, etc.; and third, the landing. The commonest type of accident is on landing.

## Type of Accidents.

## Actual Damaging Forces in Aeroplane Accidents.

The injuries sustained are akin to most high velocity accidents, but are usually more severe, as greater speed is used in aviation. They include the following: (1) Injuries due to crushing, where some part of the pilot's body gets crushed between parts of the wrecked aeroplane or between the engine and the earth. (2) Injuries due to collision with the ground, as when the pilot is thrown out or hits the ground with his head in turning over in and with the aeroplane. (3) Injuries due to impact with different parts of the aeroplane, as when the head is violently jerked forward and strikes the edge of the nacelle on the aeroplane's impact with the ground. (4) Injuries from fire. (5) Drowning and immersion effects in seaplane work. (6) Suspension effects, as when the pilot is suspended head downwards in an overturned aeroplane and is unable to loosen his safety belt; in many crashes the sudden impact of the pilot's body from petrol fumes.

any other in the treatment of fractures of the lower and upper extremities, for it is the only splint which enables the surgeon to apply in a perfectly efficient, simple, and satisfactory manner the all-important principle of extension. To some medical men the name "Thomas" was only associated with bone-setting and quackery, when it should have brought at once to their minds a genius who, by his invention of the "Thomas knee-splint," produced the greatest mechanical non-operative advance in the treatment of fractures which any man has added to our surgical equipment.

I have frequently noticed that patients erroneously associated this splint with the famous hospital of the same name, although Thomas the surgeon was in no way connected with that institution; but I feel convinced that the work of Thomas, which has been the basis of all modern success in the treatment of fractures, which has so mitigated pain and saved limbs, and which has so averted bony, nervous, vascular, and muscular troubles, will gain for that brilliant surgeon full and complete recognition as long as any records exist.

#### FIRST-AID TREATMENT.

Efficient first-aid treatment is of the utmost importance to the patient, and this necessitates—(1) training of first-aid workers; (2) supply of suitable apparatus.

The beginning and the end of the treatment of a fracture of a long bone is—(1) to replace the broken ends at the earliest possible moment; (2) to keep them in a position until Nature has joined them together; and (3) to maintain the nutrition and function of the soft parts by massage, electricity, etc.

The reduction of fracture displacement can usually be achieved by manipulation—that is, by persuading the broken ends of the bone to retrace the unnatural path they have taken; and this is effected by making one fragment a fixed point, then bringing the other into its correct anatomical position and keeping it there by exerting a steady, even, and never relaxed pull. This is the fundamental rule which underlies the efficient treatment of all fractures of long bones, and it is in this way alone that the tragedies of shortened and otherwise deformed limbs can be averted. The proper time to apply this extension to the limb is on the spot where the wounded man fell on the battlefield, or the civilian was run over in the street, and not at the regimental aid post or field ambulance in the one case, or in the city hospital in the other. This can be done with ease by means of Thomas's splint, and I wish to emphasize this point all the more because I notice that in the official St. John Ambulance manual *First Aid to the Injured*, 1921, published three years after the war, there is no mention of Thomas's splint or the way in which it is applied. Police, railway companies, institutions, and many other public bodies which are interested in training in first aid, accept this manual as the standard work upon which to depend for guidance, and it follows that, in the absence of any reference to Thomas's splint, a vast number of first-aid workers are never trained in the use of the only splint which was found of universal and inestimable value in the great war.

I shall now ask your indulgence while I describe the first-aid treatment of, say, a fracture of the middle of the femur, as a typical example of the principles involved.

Each first-aid party should carry a Thomas's knee-splint. This appliance consists of an oval iron ring, united obliquely to a length of round iron which forms the side-bars and the end of the splint. The iron ring is well padded and covered with leather. The splint can be used on either leg. It can be carried conveniently and comfortably by threading the closed stretcher through the ring of the splint and tying the side-bars to the poles. Two men are required to apply the splint, and for the sake of clearness I shall refer to these as the "operator" and the "assistant."

The operator places his right hand round the heel of the injured leg and, while exerting an even steady pull on the leg and gently lifting it, he uses his left hand to support the leg at the seat of the fracture. The assistant then carefully threads the ring of the splint over the foot and,

with his right hand, grasps the ankle, takes the extension on the leg, and thus releases the operator's right hand. The assistant runs the splint up the leg until the ring reaches the operator's left hand, when he passes his own left hand through the ring and relieves the operator's.

The operator now controls the splint which he pushes up the leg as far as it will go—that is, until the ring rests against the bony prominence of the tuberosity of the ischium.

Leaving the splint and leg in charge of the assistant the operator prepares a mechanical means of maintaining extension. He takes a pointed metal pin or skewer, about 12 inches long, and passes it obliquely through the boot so that the skewer lies between the sole of the foot and the sole of the boot. The correct angle is attained when the outer end is about  $1\frac{1}{2}$  inches nearer the toes than the inner end. When in position this "extension pin" rests on the side-bars of the splint and allows the limb and foot to be in external rotation. A piece of bandage or tape is attached to each end of the pin, and these are taken the one under and the other over the side-bars and tied in the V at the end of the splint (see Fig. 1).

When this manoeuvre is completed, the assistant, with his right hand, keeps the end of the splint raised so that the leg is clear of the ground, and, with his left hand, still supports the site of fracture. The operator takes a 6-inch bandage and, having fastened one end to the outer side-bar of the splint near the ring, passes it from side to side underneath the limb, and alternately over the inner and outer side-bars, until the whole limb, supported by the bandage, is comfortably suspended between the side-bars of the splint.

The patient can now be lifted on to the stretcher without danger of further injury to the limb. This done, a suspension bar should be applied to the foot of the stretcher and the splint suspended from it (see Fig. 2).

What has been effected is this: The ring, pressing against the ischial tuberosity, fixes the upper fragment of the fracture. The side-bars and the end of the splint being in one rigid piece, it follows that the traction put on the foot by the pull exerted between the extension skewer and the end of the splint must draw the lower fragment away from the upper in the long axis of the limb, thus making it impossible for further shortening to occur. The force required to reduce a fracture of the femur and maintain the ends of the fragments in apposition is very great, especially in the case of a simple fracture, and should only be applied when the patient reaches the hospital or other place where he is to receive prolonged treatment. In the first-aid stage all that is aimed at is the fixation of the fragments and not necessarily complete reduction, for if a very strong pull be exerted on the foot through the boot ulceration and possibly gangrene may result.

For the purpose of transport, the leg is now fixed more securely in the splint by fitting pads of cotton-wool in the spaces between the splint and the sides of the knee and ankle and applying a bandage over all, so as to include the side-bars of the splint, the limb, and the padding. The case is now ready for removal to a hospital or to the patient's home for further treatment.

Too much emphasis cannot be laid upon the fact that careful and correct first-aid treatment given in the manner described, immediately after the accident, will ensure that the fracture and the patient will come before the surgeon in the very best possible condition for further active surgical treatment.

Transport of a patient with a fractured bone insecurely fixed will certainly add to his pain and therefore increase the shock, and may also lead to any of the following serious complications:

1. The muscles, blood vessels, and nerves are liable to be lacerated and a closed fracture may be converted into an open one.

2. Manipulation is more painful.

3. Extension, which is absolutely essential, cannot be safely applied in sufficient degree to a limb which is tense with extravasated blood, for the application of extension to a limb the vitality of which is already endangered by distension may determine the onset of gangrene. Never-

theless, our aim must be to reduce the displacement without delay.

4. Another serious complication is the entanglement of the ends of the fragments in the surrounding muscle and fascia. When this cannot be rectified by manipulation, it constitutes the only condition which can prevent the reduction of displacement by mechanical means and which necessitates reduction by open operation.

#### END-TREATMENT.

From the point of view of treatment, a fracture of a long bone must be considered not only as a solution of continuity of the osseous matter involved, but also as a lesion possibly affecting skin, muscle, nerves, bone, and joints in the vicinity.

The ideal treatment of a fracture should have for its object complete anatomical reposition of the injured tissues and complete restoration of functional power to the affected part. It should therefore be the surgeon's aim to produce as the end-result of his efforts a limb which corresponds to its uninjured fellow both in function and appearance. The same general principles underlie the treatment of fractures of all long bones, and in their treatment the same results should be sought after.

The war produced an over-abundance of all varieties of fractures, open and closed, complete and incomplete, and these again were transverse, oblique, spiral, impacted, non-impacted, multiple, and complicated with every imaginable combination (see Fig. 3).

From this colossal collection of material we, from 1914 onwards, gradually gained a vast and unique experience, which definitely proved the necessity for prolonged extensions, brought about the rebirth of Thomas's knee-splint, and improved it with many additions, such as extension prop, footpiece, skate, etc., necessary for the correct alignment of the fragments, to quote only a few of the many advances which now ought to be common knowledge.

When a man with a fractured femur is lying flat on his back the sound limb and the upper fragment of the broken bone are rotated outwards at the hip to an angle of about 40 degrees. Considering this fact, it is extraordinary how large a number of fractures of the leg bones have been treated with the foot in a vertical position, with the result that the lower fragment is rotated inwards on its long axis, and when union occurs and the patient resumes the erect position the lower part of the limb and the foot are markedly rotated inwards.

In each case the actual amount of external rotation of the upper fragment can be estimated with considerable accuracy by studying the position of the small trochanter in the x-ray plates. The photograph should include the upper ends of both femora, with the foot of the uninjured limb pointing vertically upwards.

The information gained from this position of the small trochanter is also useful for another reason. It is very occasionally found that, in fractures of the middle third of the femur, the damage done may be such that muscular action counteracts the natural tendency of the limb to rotate outwards. In some cases it may just neutralize this tendency, and, in this position, the upper fragment will correspond to the vertical position of the foot. In other cases this muscular action may be still more pronounced and may actually produce internal rotation of the upper fragment corresponding to the foot being rotated inwards.

In every case the x-ray photograph to which I have referred will make the position quite clear to the surgeon, and he will be able to arrange accordingly the angle at which the foot is to be splinted.

Permanent extension is obtained by the use of glue, screws, or callipers. With careful attention glue will be found to meet requirements in about 50 per cent. of cases, but in some it will not give the necessary extension without blistering, and consequently screws or callipers must be employed.

In my experience the most satisfactory means of maintaining prolonged continuous extension in the treatment of a fracture (especially in the case of the lower limb) is by exerting adequate mechanical traction upon screws inserted into the tibia, radius, and ulna.

The operation is performed without removing the leg from the Thomas splint. The skin and the side-bars of the splint having been sterilized with 3 per cent. picric acid in methylated spirit, a longitudinal incision, half an inch in length, is made down to the bone, on the inner side of the tibia, halfway between the anterior and inner borders. The tibia is then drilled in an outward direction, the drill being held so that the point is inclined slightly towards the foot. It passes through the hard bone and medulla and just far enough to bite on the medullary surface of the hard bone on the opposite side of the canal. The drill is then removed, and a round-headed steel screw  $2\frac{1}{2}$  inches long by  $1\frac{1}{8}$  inch in diameter, held in Lane's screw-holding forceps, is placed in the hole in the bone and screwed home until it bites on the far side of the medullary canal (see Fig. 4).

The second screw, for the outer side of the tibia, requires an incision made nearer either to the foot or the knee than the first screw, and also nearer to the anterior border of the tibia. This incision is made in a transverse direction and the small amount of intervening muscle is cut across. The bone is then drilled and the screw inserted in the same way as described for the screw on the inner side.

The wounds are covered with a dry gauze and 3 per cent. picric acid dressing, which is punctured so as to allow the heads of the screws to pass through, and secured in position by a bandage. As soon as one or two turns of this bandage have been applied the extension tapes are placed in position. These consist of a double length of sterile tape, attached to an oval brass ring which is placed over the screw, and the remainder of the bandage is then applied so as to include these rings. The tapes are then tied over the foot-extension prop, in the same way as gauze extensions are fastened.

The nearer the brass rings are to the skin, and therefore to the bone, the more effective will the extension be, and there will also be less tendency for the pull to bend the screws by leverage. The upper parts of the tapes are covered with vaseline to prevent the picric acid from rotting the tape and save the screws from getting rusty.

It has been stated that traction should not be taken from the leg alone, on account of the danger of stretching the ligament of the knee-joint and producing a loose knee. This danger is quite theoretical, and a stiff knee will result if passive and active movements are not commenced at the proper time.

Having now complied with the first essentials in the treatment of a fracture of a long bone—namely, to apply extension below the seat of injury and to immobilize the limb—the next question for the surgeon to consider is the plan by which the patient may be most comfortably circumstanced for a prolonged stay on his back in bed, having in view the fact that he must be easily accessible for nursing and dressing purposes without interfering with the line of extension and consequent danger of alteration in the position of the fragments. This question of the physical comfort of the patient is all-important, for the more comfortable he is the more quietly and contentedly he will lie. The risk of disturbance of the fragments will be proportionately less and the organization of the soft parts and the formation of callus will be proportionately expedited. The practical way to obtain all these advantages is to suspend the splint and limb (see Fig. 3).

Reference has already been made to suspension of the limb, in the earliest stages of treatment, by attaching the splint to a suspension bar which fits over the sides of the stretcher, but a rather more elaborate apparatus is desirable when the patient is put to bed in the place where the end-treatment is to be carried out.

#### SUMMARY.

To sum up these remarks on non-operative treatment, I would like to repeat the following points:

1. The main object to be kept in view is union with exact apposition of the fragments. The importance of this cannot be exaggerated, for, although one cannot even then say that perfect function will be restored, and although every surgeon has seen cases in which good function is associated with defective alignment, yet

[illegible][illegible]

statistics prove undeniably that good functional results will follow in direct proportion to the success which has been attained in the endeavour to restore a broken bone to its original natural form. The finding of the British Medical Association Fracture Committee in 1912 was that 90 per cent. of good anatomical results were followed by good functional results; and my experience entirely supports that finding.

2. Each new fracture is a fresh problem, and its diagnosis and treatment cannot be controlled by a set of rules which were formulated, and did excellent service, at a time when the surgeon's vision had to be projected through his finger-tips. As I have said, x rays must be used at every stage if one is to be certain of obtaining the best results.

3. When the surgeon has to deal with a complete fracture he knows that the fragments can be displaced in any of the three dimensions of space. Unless he selects a splint which will permit of these fragments being replaced through these dimensions he cannot expect a good result from his treatment. This requirement alone disposes of such splints as Liston's, McIntire's, Clino's, internal right-angled splints for the arm, and plaster-of-Paris. In my opinion these and similar forms of apparatus ought not to be used, and should be discarded from our equipment for treating fractures, because imperfect results can only be expected to follow their employment.

As I have already said, Thomas's splints fulfil all requirements, with such modifications in minor details for the arm and the leg as are necessitated by the anatomical differences in the limbs. These splints will permit of the indispensable extension; they correct the main displacement, and their side-bars allow the surgeon free access to the site of fracture, so that he is able, with the aid of x rays, to complete any replacement of the fragments which the splint itself has not already accomplished. Thus, if after extension has been applied the x-ray photographs reveal the presence of lateral deformity, he can move either fragment in the required direction by passing a loop of bandage round the limb at the level of the displaced piece of bone and gently applying traction until the lateral error is corrected. To maintain the correct position the bandage can then be fastened to the side-bar.

Antero-posterior displacement can be corrected by a transverse band passing from side-bar to side-bar either in front of or behind the limb, according to the direction in which it is necessary to move the fragment.

No other splint of which I have knowledge will give the surgeon such absolute control over the fragments.

#### OPEN OPERATION.

When it is difficult or impossible to reposition the fragments by non-operative means, and it is necessary to deal with the case by open operation, I use Sir Arbuthnot Lane's technique.

#### Plating.

Using very light plates and splinting the limb at the same time give very satisfactory results. I make it a practice to use plates only as temporary internal splints, and aim at removing them at an early date, although this will naturally depend upon the bone that is fractured (see Figs. 5, 6, 7, 8, 9).

In the case of the tibia, applying the plate to the subcutaneous surface of the bone, and removing it on about the seventh day by opening the original incision, has given good results. For complicated fractures long plates are used, and these I leave in position for a month or six weeks, but subject to x-ray readings indicating good callus formation (see Figs. 10, 11, 12, 13).

Personally, I am not in favour of leaving plates permanently *in situ*, as they are liable to cause trouble sooner or latter.

#### Wiring.

Wiring a fracture has certain advantages over plating:

1. A smaller incision is required, less tissue is damaged, and less detachment of muscle from bone is necessary.

2. Wire is more easily applied and removed.

3. A very much smaller foreign body is introduced into the tissues.

4. Wire presses on a very much smaller area of bone, and is therefore less likely to interfere with the blood supply of the bone in its neighbourhood (see Figs. 14, 15, 16, 17).

5. It can be used and has produced good results in septic cases in which plates cannot be employed, and in some cases wiring has been known to save limbs which would almost certainly have been lost if treated in any other way.

6. Wiring combined with splinting makes it easier to correct the deformity and maintain the fragments in perfect anatomical position.

#### Bolting.

In certain complicated cases, especially in the neighbourhood of joints, it will often be found that wiring and plating are not sufficient to meet the case. In such cases I have found it more satisfactory to immobilize the bone fragments by means of a bolt which can be used alone or in combination with Lane's plates.

The accompanying illustrations (Figs. 18 and 19) show an L-shaped fracture into the knee-joint treated in this way.

### SOME GENERAL REMARKS ON SURGERY IN THE ROYAL NAVY.

BY

SURGEON CAPTAIN D. W. HEWITT, C.B., C.M.G.,  
F.R.C.S., R.N.

SURGERY has been practised in the Navy ever since the Navy began to exist; anyone who visits the old *Victory* here can see for himself the operating table in the cockpit where amputations were performed at the battle of Trafalgar, and where Nelson lay dying. It is only within comparatively recent years, however, that "set" operations have become the daily routine in naval hospitals.

Although Walter Reid had operated for aneurysms some time previously, the year 1900 really marked the birth of modern naval surgery. Previous to this men requiring operative treatment were invalided and transferred to civil hospitals.

The records of Haslar, the oldest of our naval hospitals, bear evidence that it was in 1900 that the first serious abdominal operations were performed; and it is a point of interest to note that one of the hospital sick berth staff was the first patient to have his appendix removed by a naval surgeon in a naval hospital. The actual amount of surgery done for some time afterwards varied with the initiative and courage of the staff of the hospital.

The Navy has always been a conservative service and the medical branch is no exception. Every innovation had therefore to be introduced with the greatest care and tact, and the pioneers had to guard against the least suspicion of carrying out experiments on the personnel of the fleet. They could only follow slowly, therefore, in the wake of the civil hospitals, and before attempting anything new had to be in a position to prove that there was ample justification for any surgical measures they might adopt—and, more than that, they could not afford to have failure. All the more credit, therefore, was due to them for their courage and initiative. For instance, during those early years the administration of a general anaesthetic was a most important function at which the medical officer in charge of the hospital had to be present.

The naval surgeon has always, perhaps, occupied a unique position in having to grapple unaided with all sorts of surgical difficulties in all parts of the world. He may find himself in a small ship off the west coast of Africa, or up a river in the wilds of China, suddenly confronted with organizing single-handed arrangements for an expedition miles inland. Dressings have to be provided, transport for the wounded arranged, and operations performed with little or no skilled assistance. It speaks well for him that he has been able so often to emerge triumphant from such difficulties.

To-day naval hospitals compare favourably, both as regards equipment and personnel, with similar civilian establishments, and the work carried out in them is practically the same. It is of a varied nature and only restricted

impairment of the peristaltic action of the intestine, weakness of the rectal nerves, or excessive obesity. Secondary lavatory, which made a squabbling position impossible. It might be that the construction of the lavatory was one of the great causes of constipation in modern life. A simple adjustable lavatory seat should be in every house where there were children. In how many houses were the lavatory seats suitable for children of school age? Where the case was very chronic a normal saline draught—one quart—taken at seven o'clock in the morning would act within half an hour. The lubrication of the bowel and contents was often necessary, as the faeces were dry and hard.

Dr. EDWARD FURBER said that constipation began in infancy. The nurse and mother were probably constipated themselves, and therefore they did not realize how important it was to educate the child. The child was too frequently scolded over the matter, and all its associations were thereby made unpleasant to him; it might even figure in his nightmares. Among the causes of constipation was a painful condition of the anus which was frequent in infancy after hard constipated action. In adults constipation due to drugs taken from vicious habit should not be overlooked. The speaker exhibited an American apparatus designed for a colon douche.

Dr. PERCY SPURGEON quavered with the ordinary conception of what was known as constipation, which was defined as a packing together of the contents of the bowel. Constipation appeared to him to be an inability to evacuate a quantity of faecal debris corresponding to the solid food taken. Apart from surgical or pathological conditions, constipation was to his mind entirely a habit, and due to various causes. It was not in any sense of the word a disease, but, like many habits, if neglected it might become a disease. The cause must be separately considered in the case of children, adolescents, and adults. In children, he agreed with previous speakers, it was due almost entirely to the fault of the mother or the nurse, their want of perseverance and firmness. The child was encouraged in the bad habit of putting off the natural function. On the other hand, there were many children who appeared, curiously enough, to be wilfully obstinate, and who would not evacuate even when held up. There, again, the mother did not persevere. From this failure a whole series of troubles took their rise, leading to serious results in later life. Afterwards came the misuse of aperients as a contributing cause. Proper dieting was the natural and reasonable treatment of constipation, and aperients were grossly misused, especially by those people who thought that every advertisement they saw in the newspapers was going to be a panacea. Unsuitable dietary and faulty exercises were factors which accounted for much constipation among children. Some people thought that by violently exercising the child they were going to induce its muscles to work, whereas what they were doing was merely fatiguing the muscles, which they were doing was merely fatiguing the muscularature. In the very small child irregularity of the hour of defecation was almost the natural thing. In the older child this irregularity should be discouraged in favor of regular habits. In adolescents want of supervision was an important cause of constipation. There was too much hurrying to school. Among grown-up people there was a widespread failure to realize the necessity for regular habits, not only in eating, drinking, and sleeping, but in evacuating the contents of the bowel. He maintained that it was the irregularity of the hour at which the grown-up person went to stool which had a very marked effect on occurrence of constipation. For the headache which nearly always arose from these troubles there was a growing tendency nowadays for the general public to treat themselves with aspirin, and against the misuse of aspirin in this connection he felt it very necessary to make a protest. If people would take the old-fashioned "blue pill" instead of aspirin their headaches would get better far sooner. Liquid petroleum was very useful for the child, and so, with certain reservations, was syrup of figs. One thing which he had used very much was phenolphthalein, which in reasonable doses was an excellent drug. Mr. SQUEERS, who does his boys on brimstone and treacle, based his treatment on common-sense lines, for the boys were being

## PYKNOLEPSY.

At a meeting of the Section of Neurology of the Royal Society of Medicine held on November 8th, Dr. W. J. ADAMS read a paper on pyknolepsy, a form of epilepsy in children with a good prognosis. He first described a case of his own, in which all the features seemed to point to a diagnosis of epilepsy, but which showed certain peculiarities—the great frequency of the attacks from the beginning, their sameness, their uniform mildness, and their obvious harmlessness. Prolonged treatment with bromides, iunium, and other remedies had produced no effect on the attacks. He had asked himself whether this case could be one of so-called pyknolepsy. The attacks had ceased soon after and had not recurred. Such an experience had stimulated him to search the literature and he had found that nothing had been written on the subject in England. Friedman had first described the disease in 1906 in a paper entitled "On non-epileptic absences or short narcoleptic attacks." He was followed in 1907 by Heilbrunner, and in 1921 Friedman returned to the subject, giving a very favorable account of the after-histories of his original cases. Since then numerous papers had been written on the subject, chiefly in Germany. Friedman states that the disease has only one symptom—the attacks. These begin suddenly in healthy children between the ages of 4 and 10 years and recur with certainty acted like one.

The PRESIDENT, in closing the discussion, referred to the need for more attention to lavatory construction, especially from the point of view of children. Dr. DES VOEUX, in replying, criticized the contention of some speakers that constipation was a symptom only, and not a disease. It was curious that a mere symptom should cause all the diseases which had been mentioned. He believed it might truly be described as a disease, or if not a disease it certainly acted like one.

Dr. MORREY MACLEOD was inclined to make a sneer at the further cause. Cases of very bad constipation should be dealt with by emmas.

Dr. ADAMS said that the chief cause was laziness and lack of habit formation. Defecation was associated in the child mind with threats, which was a pity. In the second decade constipation was much more common in the female than in the male, and the causes were principally the greater shyness of the female and the fact that there were still not enough sanitary conveniences in girls' schools. In the third decade he thought the condition still more common in the female, and here again shyness played a part, also want of habit, and at this period one began to see the constipation which was caused by pelvic disorders. In the fourth decade there were still more females than males among the sufferers, though the incidence was increasing among males; among females the commonest cause now was the loss of muscle power after confinement. In the next decade cases among males occurred with fair frequency, the cause being loss of tone. By the sixth decade the sexes were about equal. Here, in the case of women, constipation was apt to be caused by the hypothyroidism of the menopause. As to treatment he was strongly in agreement with those speakers who looked with abhorrence on aperients. He thought also that too much reliance was placed upon foods for children so made as to leave no residues. Exercise from the second decade onwards did a great deal of good. A very mild saline every morning was extremely beneficial, and he also praised the merits of cascara.

Dr. ADAMS, in closing the discussion, referred to the need for more attention to lavatory construction, especially from the point of view of children. Dr. DES VOEUX, in replying, criticized the contention of some speakers that constipation was a symptom only, and not a disease. It was curious that a mere symptom should cause all the diseases which had been mentioned. He believed it might truly be described as a disease, or if not a disease it certainly acted like one.

in type by the fact that no women or children are admitted. Although most of the surgery is of an emergency character amongst young and vigorous men, at the same time the dockyards and pensioners provide work of a different kind, and everything which comes along is now done as a matter of course.

Examination of the naval medical blue book (*The Health of the Navy*) for the year 1912 (a peace year, and therefore uninfluenced by the abnormal conditions during and after the war) demonstrated that here at Haslar 1,793 operations were performed under general anaesthesia.

The whole question of surgical treatment in the Navy is closely associated with that of hospital ships and hospital trains. All fighting ships in the Navy above a certain size carry one or more medical officers and are provided with a small hospital, called the sick bay, where the crew receive first aid and can be treated in bed for minor complaints which do not necessitate their transference to a hospital. The medical officers are assisted by male nurses, called sick berth staff, one or more according to the size of the ship. The larger vessels are also supplied with an operating room where urgent work can be done, and an x-ray machine. Each ship, therefore, of any size, is more or less self-contained and carries about its own small hospital with staff and equipment.

Experience has proved, however, that major cases can only be successfully and properly treated in a shore hospital or hospital ship, and that there are several reasons why it is preferable to get the patient away as soon as possible from the fighting unit.

This brings us to the question of hospital ships. Recent service in the naval hospital ship *Maine* with the Mediterranean Fleet has convinced me that a hospital ship is a most valuable asset to a fleet. She can go wherever required and form a floating hospital on the spot, where serious cases can be transferred instantly, and where skilled nursing is always available, obviating the necessity of transport to shore hospitals over perhaps rough country and in foreign lands.

The great war has had a most stimulating effect on naval surgery generally. It brought naval medical officers face to face with all sorts of new surgical conditions, and the constant association with some of the foremost surgical experts in the United Kingdom was most helpful and has left its mark on the service to-day. It is satisfactory to note that the impressions formed by several of these men, with their vast experience in civil hospitals both in the metropolis and all over the country, were very favourable to the work done by naval surgeons throughout the war. After the battle of Jutland the treatment of the wounded in some of the ships engaged was found to be so excellent that nothing further was necessary on their admission to hospital.

In naval hospitals the work is organized by the Surgeon Rear-Admiral in such a way that an experienced operating surgeon, usually a surgeon captain or a senior surgeon commander, is always on duty and available for any emergency operation. These operating officers reside in the hospital precincts, and as they have no other duties of any importance to interfere with their work operations are always carried out with the least possible delay. As an example of this, a marine who was route marching and fell out sick at 10.30 a.m. had his perforated gastric ulcer sutured before 12 noon.

It is interesting to compare the conditions under which operations take place in a naval and a civil hospital. In the Navy, practically speaking, the individual is always under the supervision of a medical officer, and it is rare to find one who is not a skilled clinician. Emergencies are promptly recognized and as promptly transferred to hospital, as there is a very complete organization for this work.

As far as the patient is concerned, he is usually a young healthy individual; he has no cares or anxieties; there is no economic question, and he usually accepts the ministrations of his surgeon in the same spirit as he accepts the orders of his captain. It is this attitude all the way through which accounts for the exceptionally favourable results which follow operative treatment, there being long

series of appendices and perforated gastric ulcers without a death or any untoward symptoms. When convalescence has been established the naval surgeon is in the fortunate position that he has complete control over his patient's diet, exercise, and on the performance of his duty for so long as he considers necessary. The patient is not cast out of hospital as soon as his sutures are removed, as may happen in civil hospitals.

As the naval hospital is a convalescent home as well as a hospital, should further residence in the hospital be undesirable, the patient can be sent home on sick leave for any reasonable period; indeed, it would be difficult to imagine more ideal conditions for surgical practice, both to the patient and to the surgeon.

It is true that the type of operation is limited by the class and sex of the patient dealt with, but the operations are varied enough.

On ten days (taken at random from the operating book) we have the following:

Two laparotomies for general peritonitis following appendicitis; 4 hernias; 5 varicose veins; 2 tonsillectomies; 1 aural polyp; 2 mastoidectomies; 1 hydrocele; 1 perineal abscess; 5 appendicectomies; 2 axillary abscesses; 1 nasal polyp; 1 wiring fractured patella; 1 ventral hernia; 1 amputation of middle third of forearm; as well as 5 other operations for various forms of sepsis.

Formerly specialists were not encouraged in the Naval Medical Service; every medical officer was supposed to be capable of treating efficiently any type of case that came along. The fact that a man should try to specialize was too often considered tantamount to an effort on his part to evade sea service or to get an easy job. Nowadays all this is altered, and there are men with high and special qualifications in various branches of surgery both in shore hospitals and with the fleets. Ophthalmology, ear, nose, and throat work, and genito-urinary surgery are all under surgeons who have been carefully trained, and our x-ray, electro-therapeutic, and orthopaedic departments are well up to date. Dental surgery has also come in for full recognition as a separate department, and we have now several qualified dental surgeons with full equipment in our large shore establishments and hospitals, as well as afloat.

Members of the sick berth staff are trained to assist in all the departments, and as they are specially selected from this excellent and intelligent body of men they soon become remarkably efficient and are a great help to the officers in charge.

I have endeavoured in this short paper to demonstrate to those of you who are unacquainted with the Naval Medical Service the rapid progress of naval surgery during comparatively recent years, and I think a walk round Haslar will convince most of you that we in the Navy are not far astern of our brothers ashore.

Time does not permit me, much as I should wish, to go into the question of treatment of several surgical problems, but I should like to bring forward as subjects for discussion the treatment of two acute affections which are common in the Navy to-day, and in my opinion, are becoming more so—namely, perforating gastric and duodenal ulcers (especially as regards the draining of the peritoneal cavity), and the methods of operating in cases of appendicitis.

Finally, I desire to thank my friend and colleague, Surgeon Commander J. R. Muir, M.B., R.N., for helping me in this paper.

#### SOME CONSIDERATIONS IN THE ESTIMATION OF PHYSICAL EFFICIENCY.

BY

GROVE CAPTAIN MARTIN FLACK, C.B.E., M.B., M.A.

[ABSTRACT.]

IN 1920 the report of the Ministry of National Service showed that, by the ordinary methods of medical examination, there was, in round numbers, in respect of 2,425,124 recruits, a shortage of 825,000 Grade I men, an excess of 61,000 Grade II men, the enormous excess of 575,000 Grade III men, and 190,000 Grade IV men. Nor were the results any more satisfactory as regards youths of 13.

Dr. Adie said that the contrast between the prognosis in these cases and cases of ordinary epilepsy in children was remarkable, according to prevalent ideas. He had been able to find cases recorded in the literature where freedom from attacks for as long as ten years had occurred. Could such cases be described as ordinary epilepsies? The spontaneous recovery which appeared to be the rule in pyknolepsy was most unlike ordinary epilepsies. In epilepsies the prognosis was especially bad in cases with repeated minor attacks and where no response to treatment obtained. And yet this was exactly what took place in these cases where the prognosis was so invariably favourable. In pyknolepsy the acme of the disease was attained at once and its most characteristic feature was the monotony and the uniform mildness of the attacks that might recur daily for many years, without the occurrence of any change in the type of attack. Mental deterioration and psychical defects, so common in epilepsies, did not occur in this other form of disease. Such great differences in the two conditions were not to be ignored. The name "pyknolepsy" suggested by Schröder was suitable as it emphasized the closely packed or aggregate attacks which were typical of the condition.

He proceeded to give some further details showing that the onset of the disease was between 4 and 10 years; its duration had varied from seven weeks to ten years, with a mean of nine years. The actual onset was sudden, almost explosively in some cases. An equally sudden termination was the rule. The most important single feature of the attacks was their extraordinary monotony. The absence of any result from treatment was so typical of the disease that a favourable response to treatment was not consistent with a good prognosis. There did not appear to be any association with a family history of epilepsies, alcoholism, or nervous slight, vasomotor disturbances, mental distress, palpitations, lassitude, or confusion after the attacks were quite foreign to the condition and were, on the other hand, more suggestive of true epilepsies. At the onset there was nothing in the attacks to distinguish them absolutely from epilepsies, and a certain amount of observation was required before a final opinion could be given. Actual falls and involuntary micturition was to be regarded with great suspicion. Until we had greater experience it was better to restrict the term "pyknolepsy" to cases that conformed absolutely to type. Abroad the condition had been accepted as being a disease sui generis. Himself would be content if he had succeeded in conveying the lesson that there did exist a form of epilepsy which was associated with a good prognosis.

A meeting of the Brighton and Sussex Medical-Chirurgical Society was held on November 1st, when Mr. H. F. Seymour read a paper on diurnal incontinence in women.

Mr. Seymour said that this form of functional incontinence of urine was very common in women over 40 years of age, especially those who had borne children. It occurred only when some effort was made which produced sudden abdominal strain, such as coughing or sneezing, or some movement which involved a sudden jerk. Women were inclined to bear this uncomfortable symptom philosophically, as one of the after-effects of childbirth, thinking nothing could be done to relieve them. The symptoms being so common, it was surprising that British gynaecologists had paid so little attention to it. Mr. Victor Bonney had lately ventilated

DIBURNAL INCONTINENCE OF URINE IN WOMEN.

A clinical meeting of the Aberdeen Medical-Chirurgical Society was held on November 1st, when Dr. W. F. Chalmers, Alexander Oostrom, in the chair, with the President, Dr. Alex. Macdonald, read a paper on diurnal incontinence in women.

Dr. Seymour said that this form of functional incontinence of urine was very common in women over 40 years of age, especially those who had borne children. It occurred only when some effort was made which produced sudden abdominal strain, such as coughing or sneezing, or some movement which involved a sudden jerk. Women were inclined to bear this uncomfortable symptom philosophically, as one of the after-effects of childbirth, thinking nothing could be done to relieve them. The symptoms being so common, it was surprising that British gynaecologists had paid so little attention to it. Mr. Victor Bonney had lately ventilated

the subject in a very able paper, from which Mr. Seymour quoted, and a series of diagrams were shown giving the anatomical relations of the parts involved. It was pointed out that the causative factor was the relaxation of the layer of unstriated muscle known as the pubo-cervical muscle-sheath, which normally supported the female bladder, and that it was the anterior third of that sheet which sagged in its relaxed state and so allowed the momentary displacement of the urethra, causing the incontinence. The incontinence was more likely to occur when the bladder contained very little urine. The rectal sphincter in women was very weak and easily dilatable, and after having been dilated to a great extent incontinence did not result.

Regarding treatment, Mr. Seymour stated that palliative measures were of no use as there was no kind of pessary operation for reinforcing the unstriated muscle fibres beneath the urethra by means of buried sutures of an unabsorbable material, inserted transversely after exposing the urethra by means of a vertical incision through the anterior vaginal mucous membrane. The operation was reported to be successful in the great majority of cases and recommended for all patients above 45 years of age who were distressed by this symptom, where there was no contraindication. It was sometimes necessary to combine with this simple operation an anterior colpoplasty if a cystocele were present at the same time.

Mr. Seymour then went on to consider another subject, the treatment of retroversion of the uterus, under three headings: (1) no treatment at all; (2) palliative measures; and (3) surgical means. (1) When a retroverted uterus caused no symptoms there was no need to treat it. (2) Regarding palliative measures, pessaries were of considerable value in the treatment of retro-displacements of the uterus, but they had only a limited field of usefulness. Pessaries should never be used for a long time in patients with a tendency to pelvic neuroses as they were often made worse by their use. Pessaries were most useful in the retroversion of early pregnancy, holding the uterus as they did in a normal position, and preventing an early abortion or incarceration of the gravid uterus. Again, pessary treatment was often called for during the puerperium when the uterus was retroverted on account of subinvolution. (3) The various operations which had been designed for the relief of retroversion were discussed and described in detail. Mr. Seymour advanced the intraperitoneal round ligament shortening operation, which was a modification of Gilliam's method. This operation done through a Pfannenstiel incision was, he believed, well-nigh faultless, and gave the best results. Moreover, it was a particularly suitable procedure during the years of potential childbearing and in no way interfered with normal labour.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A clinical meeting of the Aberdeen Medical-Chirurgical Society was held on November 1st, when Dr. W. F. Chalmers, Alexander Oostrom, in the chair, with the President, Dr. Alex. Macdonald, read a paper on diurnal incontinence in women.

Dr. Seymour said that this form of functional incontinence of urine was very common in women over 40 years of age, especially those who had borne children. It occurred only when some effort was made which produced sudden abdominal strain, such as coughing or sneezing, or some movement which involved a sudden jerk. Women were inclined to bear this uncomfortable symptom philosophically, as one of the after-effects of childbirth, thinking nothing could be done to relieve them. The symptoms being so common, it was surprising that British gynaecologists had paid so little attention to it. Mr. Victor Bonney had lately ventilated

## 18. Treatment of Fibroids.

F. NAVARRO BLASCO (Anal. de la Soc. Gin. Esp., 1923, p. 73, in *Arch. de med., cir. y esp.*, June 9th, 1923), who records three cases of hysterectomy for fibroids after treatment by x rays, maintains that x-ray treatment of fibroids is not so harmless as is supposed by patients and some medical practitioners, but that it may give rise to various complications, such as intestinal ulceration and peritonitis. In most cases, he says, it is a blind method of treatment and has the great disadvantage of producing sterilization. Surgical treatment is indicated for fibroids which are subserous, submucous, painful, of large size, suppurating, degenerating, causing compression, complicated by adnexitis, perimetritis, pyosalpinx, ovarian cysts, or umbilical hernia, as well as those occurring in young women or cases of doubtful diagnosis.

## 19. Gonorrhoea in Women.

J. A. MCGLINN (*Therapeutic Gazette*, April 15th, 1923, p. 229) considers that the majority of acute cases of gonorrhoea in women are overtreated, and that local treatment in chronic cases is usually a waste of time. The aim of treatment is to destroy the organism and prevent its growth by changing the soil of its habitat. Since the primary infection is generally in the cervix its canal must first be cleansed of discharge with bicarbonate or hypochlorite solution, and then dried with hot air or swabs before applying any germicide, the best being a warm 1 in 2,000 solution of aniline gentian violet. Frequent douching of the vagina with hot normal saline or 1 in 5,000 hot permanganate solution is necessary to prevent its reinfection from the cervix, and in order to retard the growth of the bacteria its soil should be changed by yeast suppositories. The discharge, which persists even after the cervix and vagina are gonococci-free, can be overcome by keeping the vagina dry by packing it with Fuller's earth overnight and washing it out in the morning. Urethral involvement is best treated with argyrol solution, and in involvement of the glands of Bartholin no treatment will avail short of opening up the ducts and treating the tract directly. In chronic cases the disease is latent in the cervix, Bartholin and Skene glands, and local treatment by long-continued use of the usual applications is useless because the germs are so deeply embedded that they can only be destroyed by the actual cautery or the application of radium. Involvement of the glands of Skene necessitates laying them open and cauterizing their entire surface, and the glands of Bartholin should be completely dissected out or destroyed by the cautery. Post-operative treatments should be given to prevent the danger of cervical stenosis after cauterization.

## Pathology.

## 20. The Pathogenesis of Intestinal Infectious Ulcers.

S. YANAGISAWA (*Kitasato Archives of Experimental Medicine*, February, 1923, p. 33) gives the results of a series of experiments on mice and guinea-pigs undertaken in an endeavour to throw some light on the mode of production of the infectious intestinal ulcers of man. It occurred to the author that the subject could only be satisfactorily studied by adopting in his experimental work the path of infection as it occurs in man, and accordingly he administered by the mouth bacilli which he was able to isolate from accidental epidemic intestinal ulcers in the mouse. By this means intestinal ulceration was successfully produced, and was exactly similar to that encountered in typhoid fever, appendicitis, and the like. Microscopical appearances indicated that the infection was enterogenic, and no evidence of a haematogenic origin was found. On reaching the lumen of the bowel bacteria enter the crypts and there, especially at the neck of the crypt, penetrate between the epithelial cells of the subepithelial layer; then, by way of lymph spaces, they reach the tissue surrounding the follicles, and eventually penetrate the latter and produce an abscess. The author offers several suggestions as to the manner in which the bacteria penetrate the epithelial covering. First, the stagnating organisms in the lumen of the crypts may develop substances which injure the epithelium and lower its resistance to infection; secondly, the epithelium just above the follicle is irregular and deficient in goblet cells, a characteristic of low resisting power; thirdly, an extensive absorption of bacilli by leucocytes was observed. The stages in development of the experimental ulcers were as follows: within forty-eight hours hyperaemia and slight erosion of epithelium could be made out; within seventy-two hours there was a phlegmonous inflammatory process with hyperplasia of the follicular tissue, cellular infiltration, and more or less advanced necrosis; in ninety-six hours these changes

had greatly increased—the stage of ulceration and abscess formation. In the guinea-pig the eventual tendency was towards a definite process of healing by granulation, resulting in the production of a scar, whereas in field-mice the most common termination was perforation.

## 21. The Importance of Metallic Salts in Immunization.

VERY interesting results have been obtained by L. D. WALBURN and J. R. MÖRCH (*Ann. de l'Inst. Pasteur*, April, 1923, p. 396) in the production of diphtheria antitoxin in horses and goats by the administration of various metallic salts during the period of immunization. It was found that the intravenous injection of manganese chloride or of cobalt chloride—particularly the former—resulted in the production of an antitoxin of considerably higher titre than that usually obtained. Not only, however, was this effect obtained when the salt was given at the same time as the toxin, but if it were injected altogether apart from the toxin, during the period when the antitoxin content of the serum was declining, it gave rise to a sudden ascent in the titre of the serum. The manganese injected into the blood stream rapidly disappears from the circulation, and is largely excreted by the intestinal mucosa. In horses receiving daily injections of the chloride the manganese content of the different organs was found to rise proportionally to the quantity of the metal administered. A close relation was established between the ability of the liver to retain manganese and the ease with which antitoxin was elaborated by the animal. The effect of certain metals on the production of agglutinins to *B. coli* in the rabbit showed that there was a correlation between the atomic weight of the metal and the quantity of antibody obtained. Just how the metals act in the mechanism of antibody production is not clear, but certain observations rather suggest that their function is of a catalytic nature.

## 22. A New Sero-diagnostic Method of Cancer.

A. CABANIS and C. FOULQUIER (*C. R. Soc. de Biologie*, April 21st, 1923, p. 1011) report the results of a study they have made with a view to confirming the value of the sero-diagnostic test for cancer, which was published recently by Botelho. Their technique was the same as that originally recommended, except for the substitution of a 5 per cent. solution of lactic acid for the formalized citric acid. Their observations included an examination of 140 serums—18 from patients affected with cancer, 34 from cases of diverse nature, 6 from lying-in women, and 82 from the venereal department. In 77 per cent. of the cancer cases the reaction was positive. It was also positive in 59 per cent. of the cases suffering from diverse affections—affections which included such diseases as liver abscess, benign tumours, Pott's disease, anthrax, uraemia, and typhoid fever. Of the lying-in women, 5 gave a positive reaction, while of the 82 serums from the venereal department only one positive reaction was found. From an analysis of these figures the authors find that in every case in which the urea content of the blood exceeded 0.5 gram the reaction was positive, and they are inclined to regard the reaction as determined by the effete products which poison the organism in certain diseases. It is not specific for cancer, nor does it distinguish between a benign and a malignant tumour; as the test is positive, however, in 75 to 77 per cent. of cancer cases, they consider that it may be worth while employing it as an aid to diagnosis.

## 23. Hepatic Insufficiency in Enterocolitis.

FOR the last two years R. SAVIGNAC and M. DE FOSSEY (*Bull. et Mém. Soc. Méd. des Hôpitaux de Paris*, May 24th, 1923, p. 719) have been studying the question of hepatic insufficiency in cases of enterocolitis. Their mode of procedure has involved the estimation in the urine of the nitrogenous distribution, Maillard's coefficient, urobilin, and the biliary pigments and salts, and in the blood the amount of cholesterol, the degree of cholaemia, and the presence of digestive haemoclasia, with in some cases the estimation of the titre of the sugar, of the residual nitrogen, of the nitrogenous relationship, and of the resistance of the red blood corpuscles. The patients under consideration numbered 17, and were suffering mostly from colitis, either with diarrhoea or with constipation. In no fewer than 13 of them signs of hepatic insufficiency were found, generally indicated by hypercholesterinaemia, hypercholaemia, digestive haemoclasia, or by disturbance of the nitrogenous relationship. Dividing the functional alterations into two main categories—those affecting the biliary metabolism and those affecting the nitrogenous metabolism—they find that it is the former which are the more marked. They were unable to establish any definite relationship between the various functional disturbances, so as to obtain a measurement of the degree of hepatic insufficiency, nor were they successful in correlating the different signs with the clinical type of disease studied.

and BE SATISFIED

Wherever they sell Tyres, they recommend DUNLOPS.

it

BRITISH  
MADE

HAVE you ever realised how much your petrol consumption? Have you ever considered this fact when buying your tyres? Dunlop Cord tyres are built specially with a view to economical running. The Dunlop multiple ply cord construction enables these world-famous tyres to run with a minimum amount of stress over the most indifferent surfaces. No engine energy is wasted. This means even acceleration and an economical petrol mileage to the gallon. They also give you record mileage. Think of this next time you buy tyres and insist on "Dunlop Cords."

## Reviews.

### DISEASES OF THE BREAST.

DISEASES of the breast have attracted a host of writers and investigators, and judging from the number of recent publications the popularity of the subject is certainly not on the wane. Mr. WILLMOTT EVANS in his recent book entitled *Diseases of the Breast*<sup>1</sup> has endeavoured to describe the present state of knowledge, and has not hesitated to express his own views on many of the problems which remain unsolved. Although no new or startling facts are revealed, he has drawn widely from the literature, and discussed the subject with considerable adroitness. A pleasing feature of his book is the number of illustrations. In all there are 106, of which fifteen are coloured. Mr. S. A. Sewell is firmly establishing his reputation in the art of illustrating anatomical specimens. Not only is the anatomical structure of his drawings true in detail, but the setting is artistic, and the stereoscopic effect well accentuated. The early chapters deal with the anatomy and physiology, examination, and anomalies of the breast. The nipple is discussed in four chapters, then follow the various inflammations of the breast, cysts, and tumours; diagnosis, prognosis, and operations for carcinoma of the breast are then discussed. The concluding chapters deal with skin grafting, the history of operations for mammary carcinoma, the treatment of inoperable cancer, and the diseases of the male breast. In the chapter on anomalies of development there are some interesting remarks and quotations on mammary deficiencies and redundancies. Attention is drawn to the anomalies of the sterno-mastoid, and sometimes of the ribs in the condition of amazia. Paget's disease is discussed under two heads—the eczema type and the psoriasis type. As to the etiology Mr. Evans quotes Sampson Handley, who considers that carcinoma starts in the smaller ducts and that the eczema is secondarily caused by lymphatic obstruction.

All the various views on the causation of chronic mastitis are considered. The one favoured by the author is that it is due to chronic toxæmia, and his dictum on the treatment is that when in doubt it is better to remove the breast than wait for carcinoma to develop.

On the subject of metastases in bone from carcinoma of the breast the author expresses agreement in the main with Sampson Handley's permeation theory, although he is inclined to think that embolism is responsible for some of them. It is surprising that the recent work of Piney has not been included; it supports the view that the blood stream is responsible for the dissemination of bone metastases. He has pointed out that these secondary tumours arise in the red marrow at the proximal ends of the long bones. Here the blood stream widens out and is slowed, factors favourable to the lodgement and growth of malignant cells in circulation. Moreover, he can find no evidence of lymphatics in bone to sustain Sampson Handley's theory. Mr. Evans draws attention to the fact that the ordinary carcinoma cell is larger than a pulmonary capillary, and that *a priori* secondary carcinoma in the lung should be common, which is not the case. Later we are asked to accept the permeation of cancer cells along lymphatics and their transcoelomic migration. Why, then, cannot we assume that these cells permeate through the capillaries in the same way, and in circumstances—the alternate expansion and collapse of the lung—far more favourable to their propulsion?

The author quotes what seems to be a convenient method of distinguishing quickly morbid growth from healthy tissues. It consists in immersing the part removed for ten minutes in 5 per cent. nitric acid. The tumour and gland substance then appear as a white opaque mass, while the surrounding fibrous tissue and fat become swollen, homogeneous, and clear. The etiology of carcinoma is well discussed, and the author expresses the opinion that only the parasitic theory of the origin of malignant disease can offer an adequate explanation of all the phenomena to which a malignant growth can give rise.

<sup>1</sup> *The Diseases of the Breast*. By Willmott H. Evans, M.D., B.S., B.Sc., F.R.C.S. London: University of London Press, Ltd. 1923. (Demy 8vo, pp. xii + 495; 106 figures. 25s. 6d. net.)

This book forms a valuable contribution to the literature on this subject, it is well up to date, and at the same time gives all the practical detail so indispensable so far as the diagnosis and treatment are concerned.

### HEART DISEASE AND ITS TREATMENT.

So much has been written on diseases of the heart in recent years that one is tempted to doubt the necessity for any new publication unless to communicate some fresh discovery. Dr. W. D. REID of Boston considers that the very greatness of the advance in recent years necessitates the redrafting of our knowledge of the subject so that the newer facts may be correlated with older methods that have stood the test of time, and this he has attempted to do in his book on *The Heart in Modern Practice*.<sup>2</sup> He also thinks that the time has come to depart from the common plan of dealing with diseases of the heart from the structural standpoint and that an attempt should be made to discuss them from the etiologic aspect, so that several chapters need not be read to find out the effect, say, of syphilis on the circulation, even though the plan at times leads to some overlapping.

The book is divided into five sections. The first deals with preliminary considerations; it treats of the anatomy, physiology, and methods of examination, physical and graphic, and closes with a chapter on the classification of heart disease. Illustrative tracings from the polygraph and electro-cardiograph are given, but the polygrams are not always sufficiently clear to make them really useful for diagnosis to those who have not already a knowledge of these methods. In his classification the author deals first with types of disease according to their etiology, then with functional conditions, and lastly with structural lesions. In the succeeding sections these three groups are treated more in detail. The allocation of chapters to rheumatic heart disease, cardio-vascular syphilis, arterio-sclerotic heart disease, irritable heart, and other conditions, constitutes the best feature of the book, though the reader will look for a little more detail in parts. In the section on functional conditions it would have been better to have the illustrations alongside the text, where they would be particularly useful. The fact that most are given in the first section hardly meets the convenience of the reader.

The last section deals with treatment in general, although this subject has been taken up in other parts of the book. In discussing digitalis therapy the Eggleston method is described in detail as being the standard in America. There is an appendix of about 65 pages devoted to illustrative cases, but many of these could have been curtailed without diminishing their value. There are many good points in the book, and the few plates illustrating structural conditions are well produced. We hardly think, however, that it is destined to become popular in this country.

### A CONDENSED ENCYCLOPAEDIA.

*Lippincott's Quick Reference Book for Medicine and Surgery*<sup>3</sup> by Dr. REHBERGER is frankly a compilation. The author claims nothing as his own in the work except the plan, the selective judgement employed, and the great labour involved. Its matter is culled from modern medical teaching and coloured by the varied experience of one who has been an isolated country doctor, and feels that he knows the needs of the general practitioner. He has aimed at accomplishing a critical sifting of the important modern literature, a selection of all that is useful and needful in bedside therapeutics, and a rearrangement of this mass of knowledge for purposes of quick reference, making it immediately available for practical needs. The magnitude of the undertaking may be gauged from the fact that the book, consisting of eleven parts, deals, in encyclopaedic form, with the following subjects: (1) General medicine and surgery, including the diseases of infancy and childhood; (2) gynaecology; (3) genito-urinary diseases; (4) obstetrics; (5) skin diseases; (6) diseases

<sup>2</sup> *The Heart in Modern Practice: Diagnosis and Treatment*. By William Duncan Reid, A.B., M.D. Philadelphia and London: J. B. Lippincott Company. 1923. (Med. 8vo, pp. 352; 5 plates, 27 figures. 25s. net.)  
<sup>3</sup> *Lippincott's Quick Reference Book for Medicine and Surgery*. By George E. Rehberger, A.B., M.D. Philadelphia and London: J. B. Lippincott Company. 1922. (Sup. roy. 8vo; 151 figures. 63s. net.)

of the eye, (7) ear, (8) nose, and (9) throat; (10) orthopaedics, including fractures and dislocations; and (11) drugs—the whole field of practical medicine except psychiatry. To confront the solid phalanx of modern medical works and bring it within the covers of a single volume of not more than 7 lb. in weight (the pages are not numbered) is a decided *tour de force*. To the practical utility of the work the author himself bears witness, and in presenting it to his fellow practitioners he expresses the hope that it will be as useful to them as it is to himself.

That great condensation in the descriptions should be a character of a work of this kind is inevitable, although there are considerable differences observable in the amount of detail given under the various headings, depending, doubtless, on the relative importance attached to each subject by the author, from the point of view of general practice. It is possible that in some instances condensation has been excessive. For instance, taking a few examples at random: no room has been found for clear distinction between cervical and corporeal carcinoma of the uterus, nor for the important diagnostic information to be obtained from inspection and palpation of the cervix in that disease; the entire subject of carcinoma of the breast is dismissed in some one hundred and thirty-six words; and some seventy-five suffice for carcinoma of the oesophagus. No mention is made of the complications of the latter disease, such as perforation of the bronchi, although these probably appear under other headings. On the other hand, many subjects are dealt with in considerable detail. Such is the case with regard to food values, to which ten pages are allotted; the details given extend to such matters as the percentage of fat in chicken-gumbo. For ascertaining information on isolated facts the book should prove of great use, but in the fundamental matter of the knowledge of what may be called the natural history of diseases the general practitioner will still resort to other works in his library.

#### SANITATION IN INDIA.

*McNally's Sanitary Handbook for India*,<sup>4</sup> revised by Major A. J. H. RUSSELL, has now become one of the recognized textbooks for students in the Madras Medical College and for the classes of sanitary inspectors. It is addressed primarily "to the educated classes, in the hope that it may afford them information which is important to all and which may serve to benefit them and, through them, the great uneducated masses of the people." The inculcation of the principles of sanitation is the main object of the volume; detailed descriptions of various types of sanitary structures, such as latrines, are therefore omitted. Although written for the Madras Presidency, it applies, with a few exceptions, to all parts of India, and it is nearly as applicable to tropical countries generally. It should, therefore, prove of value in England to medical and civil officers and others who are preparing to go to India or other tropical regions. Written in clear language and dealing with the broad principles of the subject in close association with practical requirements, the book might be read with advantage by English students as an introduction to the more detailed study of hygiene. In India, where even in large towns the majority of the population lives in tiny mud huts, it would seem hardly possible to overestimate the importance of disseminating knowledge of the kind contained in this book. The value of propaganda work has during recent years come to be more and more recognized and is now classed among the regular duties of the medical officer of health. The whole of the health officer's staff of sanitary inspectors is directed to assist in this important duty and every effort is made to co-operate with voluntary workers' associations. No advance in hygiene can be looked for until the sanitary conscience of the people is awakened, and for this the education of the masses needs to be taken in hand. Of the truth of this no better illustration could be given than the native attitude in regard to water pollution.

<sup>4</sup> *McNally's Sanitary Handbook for India*. Sixth edition, revised and rewritten by A. J. H. Russell, M.A., M.D., Ch.B., D.P.H., D.T.M., Major I.M.S. Madras: Government Press. 1923. (Demy 8vo, pp. viii + 476. 4 rupees 8 annas.)

There is no lack of good principle in this matter, for water pollution was forbidden by the ancient religions. Valmiki says, "there is no higher sin than that of polluting drinking water." Although the views of the ancient teachers is in complete accordance with modern views of sanitation, very little attention is paid by the orthodox to their excellent injunctions. A valuable suggestion, applicable to other countries besides India, is that the rudiments of hygiene should be taught in all elementary schools; and some sensible remarks are made relating to the manner of introducing reforms. Existing arrangements, it is stated, faulty though they be, should not be destroyed until efficient substitutes have been provided. Small and partial measures can often be carried out where larger are impossible, and such measures are by no means useless if they are the first steps to further improvement; but, unfortunately, in India "the best" has been too often the enemy of "the good," and as a result even small and partial advances have been indefinitely postponed.

#### THE PSYCHOLOGY OF REASONING.

BOTH the general reader and the student of psychology will be glad to possess in English form *The Psychology of Reasoning*,<sup>5</sup> by E. RIGNANO, Professor of Philosophy in the University of Pavia. The book, which has been carefully translated by Winifred A. Holl, owes its origin to the sense of uneasiness and discontent into which the author was thrown by the perusal of some of the best treatises on logic—that science which Russell has described as "one in which we never know what we are talking about, nor if what we say is true." These treatises failed to explain the nature of the logical or reasoning faculty, though purporting to indicate the laws which govern its proper functioning. In order to arrive at an understanding of what reasoning essentially is, the author analyses the simplest and most elementary forms of the process, such as are made use of in the affairs of everyday life. From the study of such cases he arrives at the conclusion that reasoning is nothing else than a series of operations or experiments performed mentally; we do not perform them actually because, by a series of similar experiments that have been really accomplished in the course of our previous experiences, we already know their respective results. The final experimental result, observed with the mind's eye, constitutes the "demonstration" or "conclusion" of the reasoning. This enables us at once to understand why, when we start from certain premises in agreement with facts, we are able to arrive at results similarly in perfect agreement with other facts; in short, how it is possible for the logical process to give us a representation of reality; the reason being that the logical process is identical with the perceptual reality itself, operated by means of the imagination instead of actually. The author's explanation, further, enables us to trace with great clearness the sources of error and fallacy to which the reasoning process is subject. It has been said that reasoning cannot lead to new discoveries, since we start with premises consisting of facts already known and since the conclusion is implied in the premises. The author disposes very effectively of this objection by showing that the imagination proceeds by creating new combinations with old mnemonic elements, and that many of the greatest discoveries have been made in this way, new combinations of old facts indicating conclusions not previously known and which have subsequently been verified by actual experiment. Having ascertained the nature of the reasoning process, the author proceeds to trace its development from the concrete to the abstract form, and in this connexion he makes some interesting observations on the notion of "concepts" and their graphic representatives the "common nouns." The first terms in language are stated to have been common nouns, the use of which was to furnish an "affective classification" of objects—that is to say, a classification based on the needs or interests of the individual. The word "poison," for instance, represents no object, but a class of multifarious objects all possessing one point of affective significance.

<sup>5</sup> *The Psychology of Reasoning*. By Eugenio Rignano. Authorized translation by Winifred A. Holl. London: Kegan Paul, Trench, Trübner and Co. 1923. (Demy 8vo, pp. viii + 355. 1s. 2d.)

Dr. Hope strongly urges the erection of a modern abattoir suitable position and the buildings are so congested that meat and meat market in keeping with other branches of public health work in the city. He compares by means of excellent photographic illustrations the modern slaughterhouses in Edinburgh with the Liverpool buildings. If the Liverpool

Concepts, therefore, are concluded to be, not things of a perceptual order, but groups of affectively equivalent things. In order to verify the results of his analysis of the nature of reasoning, the author undertakes an examination, from a psychological point of view, of the logical process as it is shown, he considers, in its highest forms in mathematical reasoning. He argues that the fundamental nature of reasoning, as a series of merely imagined operations or experiments, remains without change even when an abstractness pushed to its extremest limit and an excessively complex symbolic form might at first sight seem to conceal this fact.

Although the explanation given of the nature of the reasoning process is relatively simple, the process itself, the author admits, is complex and the resultant of the interplay of a variety of mental activities. To obtain an understanding of the psychological phenomena of which reasoning consists, it therefore became necessary to analyse these phenomena and to reduce them, as it were, to their lowest terms. Thus the author, proceeding from the more to the less complex phenomena, finally arrived on the one hand at sensorial mnemonic reproductions (evocations of past sensations), and on the other at affective tendencies. It was possible to regard either of these as the most elementary of all psychological phenomena on whose interplay all the others depended, but Professor Rignano has succeeded to his own satisfaction in relating both to a quite general and fundamental property of life, which he had already emphasized in his biological writings. The result has been that the work which was conceived as devoted entirely to reasoning has ended as a treatise on Psychology. The fundamental property referred to is "the tendency of the organism to maintain or to restore its stationary or normal physiological state," and the manner in which the whole superstructure of psychology is built up on this single foundation cannot fail to interest the reader.

#### THORPE'S DICTIONARY OF APPLIED CHEMISTRY.

A new edition of a standard work of reference tends ordinarily to follow the lines of previous issues in general character and features. A new arrangement may in some cases be evolved based on the experience gained of the needs of persons who have used the earlier edition, or an expansion of subject-matter may be rendered necessary by new discoveries; but, if after the work has passed through successive editions, and any tendency to variation is followed by a return to type, it is a sure criterion that the work is deserving the appellation of "standard." This rule applies eminently to Thorpe's *Dictionary of Applied Chemistry*, of which Volume IV<sup>a</sup> has been issued. In it the quality of the work is well maintained in the character of its contents and in the completeness and recency of the information given. Containing as it does a mass of information known to chemists a generation ago it might have been expected that under certain headings, notably those referring to common materials like limestone, a simple reprint from the last edition would supply all the needful data. Revision has, however, been extended even to subjects of this kind, and signs are everywhere evident that close attention has been given to adding what is likely to be useful and deleting what is of doubtful value. Only a comparison side by side of the articles in this edition with those in the last will show how well the work of revision has been done. Several contributors to the last edition are represented by articles in the present. These include E. F. Armstrong, Herbert Ingle, A. G. Perkin, T. Rose, and L. J. Spencer; among the new contributors are G. Barger, to whom has been allotted a number of articles on vegetable substances having economic relation to medicine; C. T. Bennett, who has revised the subject of essential oils; and H. E. Watt, who has dealt with nuxvomica and opium. The article on opium includes a summary of the newer facts relating to the constitution of morphine and contains much to interest those who have been attracted to this subject by the hope

of finding an explanation of physiological action in chemical constitution. The monograph on matches is a classical article. It might have been fittingly bound in a separate cover and would have formed a complete treatise on the manufacturing aspect of the industry. As, however, it contains much other matter than applied chemistry, and since available space forms the chief embarrassment to compilation, there is here an obvious danger of inroad in favour of non-chemical technology on the space properly due to chemical matters. In this connexion it is to be noted that whereas no less than twenty pages are devoted to matches, the subject of margarine occupies not much over three. Apart from the subject of matches there is no conspicuous redundancy of matter disproportionate to the scheme governing the whole dictionary. When it is realized how closely the methods and secrets of chemical manufacturers are guarded, the total sum of information here published is very remarkable. It is clear that the new edition is to be fully worthy of its predecessors.

#### NOTES ON BOOKS.

*The Causes of Cardiac Failure*<sup>1</sup> is one of the series of Harvard Health Talks delivered in the medical school of Harvard University to give the public modern guidance on important medical subjects. Dr. W. H. ROBEY points out that it is and always has been quite unscientific to give "cardiac failure" as a cause of death, and adds "in signing a death certificate the best trained physicians have not within the lifetime of many of us given such a meaningless cause." In New York and Massachusetts the death rate from heart disease is higher than that from tuberculosis, but rheumatic fever has become less common, probably from increased attention to oral sepsis. Dr. Robey rightly lays much stress on the prevention of cardiac disease by the detection and removal of focal infections, and describes as potential heart disease the conditions of recurrent infection that may attack, but have not yet damaged, the heart.

The June number of the *Annals of Medical History*<sup>2</sup> has on its cover the portrait of Joseph Leidy (1823-91), the wonderfully versatile naturalist who became Professor of Anatomy at Philadelphia in 1853. According to Dr. W. S. Middleton's interesting sketch of his life, Professor Leidy—a relative of Franz Leydig, the well known Bonn biologist—bore a strong resemblance to the conventional Christ in facial expression and was frequently so addressed by children; in addition he appears to have been one of the most charming and modest of men, intellectual giant though he was. This centenary article forms an appropriate sequel to that of his professorial chief and predecessor, William Edmonds Horner, contributed to the spring number of this periodical by Dr. Middleton. The frontispiece is a reproduction of Bernardino Luini's painting of Saint Roch, the patron saint of the plague-stricken, with a bubo on his left thigh; there is an illuminating note on the saint by Dr. Charles Greene Cumston of Geneva, the president-elect of the Fourth International Congress of the History of Medicine, to be held at Geneva in 1925. The stirring story of Louis Heermann's thirty-two years' service in the United States Navy, well told by Captain F. L. Pleadwell and Lieut.-Commander W. M. Kerr, contains a picturesque description of New Orleans when Heermann went there in 1810, only seven years after it was acquired from France. Dr. J. Preston Maxwell and J. L. Liu give an interesting analysis of a Chinese household manual of obstetrics, written about A.D. 1661, which, though not constantly up to date, lays much stress on pre-natal treatment, which is stated to be so good that no medicines are needed. The "Outlines of the History of Medicine in Lower Canada" is the title of an elaborate article by Dr. M. Charlton, the first instalment of which deals with the conditions under the French régime (1608-1759).

Dr. CECIL WEBB-JOHNSON's book on *Diet for Men*<sup>3</sup> is a popular work which forms a companion volume to *Diet for Women* by the same author. After an introductory chapter in which the inadequate instruction in dietetics in medical education is stigmatized, the writer discourses pleasantly of the various forms of diet, the use of alcohol and other stimulants, diet in sickness and obesity, the effect of emotion on food, the diet of a man over 40, and kindred topics.

## Ireland.

QUEEN'S UNIVERSITY CLUB, LONDON.  
A large informal meeting of students and graduates of the Queen's College and Queen's University, S.W., on Thursday, at the Hotel Belgrave, was unanimously decided that a Queen's University Club, London, be formed, and a committee was appointed to draw up rules and to arrange for another meeting at as early a date as possible. The first annual dinner dance of the club, which is being preceded by a short business meeting of members, will be held at the Criterion Restaurant on Thursday, December 13th. Graduates and former students wishing to become members or to receive invitations are requested to communicate with the honorary treasurer, Mr. R. A. Kerr, 17, Wimpole Street, W., or the honorary secretary, Mr. W. McK. H. McCullagh, 152, Harley Street, W.

DEATH OF DR. WALLACE BEATTY.  
We regret to announce the death of Dr. Wallace Beatty, which occurred on November 8th at his residence, 38, Merion Square, Dublin, after a very brief illness. Only a few days earlier he was engaged in his medical duties; a heart attack, complicated by influenza, was the immediate cause of death. He was one of the leading members of the profession in Ireland, a most painstaking and skilful practitioner, and one of the most lovable of men. As chief physician of the Adelaide Hospital, where he succeeded the late Dr. Little, he enjoyed the respect and esteem of the medical and nursing staffs and of his patients. Dr. Beatty was born in 1853. He received his earlier education at the

is to maintain its reputation as a progressive party it cannot afford to ignore the well timed medical officer of health.

THE REV. AND SARFORD HOSPITALS SMITHING TRUST.  
to receive a cheque representing the total subscribed to the Lord Mayor's Smithing Hospital on Councilor Cunliffe took office as Lord Mayor return made from thirteen Manchester and pits and found that their finances were in a condition. He opened a shilling fund hoping 0 million shillings, and, organized by Mr. Watson, £73,000, or 1,466,000 shillings, had been by three-quarters of a million subscribers. This is the largest ever raised for a charity in Manchester and Salford hospitals.

## *Nova et Vetera.*

### AN EIGHTEENTH CENTURY PRACTITIONER'S LEDGER.

THROUGH the courtesy of Mr. C. F. Harriss, Solicitor of Newport, Salop, who is Secretary of the Shropshire Panel Committee, we have been able to look through the professional ledgers of an eighteenth century medical practitioner, William Coyne, of Holywell, Flintshire. These leather-bound volumes, three in number, are of uniform size and cover a period of more than a quarter of a century; the earliest entries refer to the beginning of the year 1746 (O.S. 1745), and the last are dated December, 1773. All that Mr. Harriss can say about the books is that he found them when clearing out one of the attics of his office, where he has every reason to suppose they had lain for over a hundred years. The firm of solicitors of which he is now the head dates back to the eighteenth century, and the distance from Newport to Holywell across the Welsh border is not great.

In shape and size the ledgers correspond with a country doctor's day-book of the present day; the pages are faintly ruled for the dates, and for pounds, shillings, and pence; the entries are in several handwritings of varying legibility. Mr. William Coyne was evidently a country apothecary in a good way, and, like so many of his contemporaries, he not only compounded and supplied drugs, but prescribed remedies and visited patients. Occasional entries show that he dressed wounds and set fractures; records of venesection ("V.S. in brach. 1s.") are fairly frequent; of midwifery practice there is no trace. The records make it plain that, though sparing in phlebotomy, he drugged his patients as copiously and as often as any practitioner of the time.

The ledgers form a straightforward record of things supplied and charged for, with little or no comment, and scarcely any touches which reveal anything of the man himself. The various accounts are arranged under the name of the householder or that of the individual patient. Many of these were persons in humble circumstances—gardeners, joiners, miners, and such like—but the practice would nowadays be described as "mixed." The more prosperous patients included members of the landed gentry, a merchant or two, "Mrs. Jones next door," several "officers," many farmers, and the local exciseman; grocers and butchers and publicans, a perruque-maker, and, in short, every kind of tradesman, large or small; together with the local attorney and schoolmaster and other professional men.

The mainstay of the practice was the head of the house of Mostyn. As is seemly, the first folio of the first volume opens with the record of William Coyne's enormously long account with Sir Thomas Mostyn, of Mostyn, and his successor in the baronetcy. During the twenty-eight years covered by the ledgers, many of Coyne's patients were members of the Mostyn family, who are prominent in the district to this day. Thus, the eleventh baronet, Sir Piers Mostyn, has a seat in Flintshire, and Lord Mostyn, the third baron, owns Mostyn Hall, Holywell. Sir Thomas, and after him Sir Roger, were a considerable source of revenue to Mr. Coyne: scarcely a week passed without several items being charged to the baronet's household account. The usual fee for a journey to Gloddeith was one guinea, and five shillings to Mostyn Hall. In addition to this visiting fee, the baronet was debited with various amounts for medicines supplied on the same day to any members of the family or of the retinue or of the livestock who happened to be ailing at the time. Thus on one very moderate afternoon Master Daniel, Master Tommy, and Miss Mostyn (who was bled as well) all needed doses of Pulv. Alterat.; Betty the housemaid had *Haust. Purg.*; and *Flor. Sulphur.* and *Bol. Armen.* were prescribed for occupants of the stable. The household was large and the outdoor servants and other retainers numerous. Mr. Coyne's patients among the indoor staff included the housekeeper and the cook, footmen, housemaids, laundrymaids, dairymaids, kitchenmaids, and turnspits, together with the Rev. Mr. Edwards the domestic

chaplain, Mr. Lloyd the steward, and Mrs. Trim the nurse; the outdoor staff included gamekeepers, grooms, coachmen, ploughmen, postillions, husbandmen, poultry women, cowmen, carters, and stable-boys. Besides these, Sir Thomas Mostyn made himself responsible for medical attendance upon unidentifiable persons such as Mr. Wynne and Mr. Blundell, who may have been visitors or perhaps resident librarians, and upon ancient retainers described as "Old Ellis," "Old Richard," "Old Mostyn," and the like. The account was discharged in lump sums at odd times by the house-steward.

Another long account, which drags on from folio to folio in the third volume, is that for visits and medicines to the household of Lord Grosvenor at Halkin. Some loose sheets of paper, preserved with the ledgers, include a stained and blotted fragment from the day-book of 1757; also a list of Mr. Coyne's principal patients in the year 1769 together with the sums due to him from each. On this appear the names of Lord Grosvenor, Sir Roger Mostyn, Bt., the Dowager Lady Mostyn, Sir Watkin Williams Wynne, Bt., and a considerable sprinkling of the clergy.

Looking through the ledgers we find entered up under the various patients' names innumerable pills, juleps, electuaries, mixtures, draughts, powders, boluses, drops, infusions, decoctions, linctuses, apozems, elixirs, and stomachic tinctures; also outward applications—plasters, balsams, liniments, embrocations, blisters, dressings; and, every now and then, the administration of a clyster. Manna was often supplied, presumably for the nursery. The endless tale of dull medicaments is relieved by occasional items such as "Fruct. limon. ii, 4d.," "Six large bladders," "A bottle of bitters, 4s.," "Best gold leaf, 2 books, 3s. 6d." In Widow Morrell's account "a quire of writing paper, 6d." appears several times; and, stranger still, Edward Roberts, Esq., of Denbigh, is debited with a silk plaid waistcoat at £2 2s.

Mr. Coyne's surgical practice was not extensive. It was confined for the most part to emergencies, such as the reduction of fractures and dislocations, and attention to injuries. At rare intervals we find records of minor operations; for example, "opening ye sinus and dressing," "opening a tumour in his groin," "scarifying," "amputat. digit. and cure."

An astonishing account is that of Miss Salisbury. It opens in the third volume under date November 18th, 1769, and continues through fifteen folios, each containing fifty or more separate entries. The last item is dated June 10th, 1771, but the record, though broken at that point, was continued in another volume, lost long since. Between those two dates, some eighteen months apart, never a week passed, and seldom a day, without Miss Salisbury receiving a draught or some aromatic spirits or a bottle of Bristol water from the attentive Mr. Coyne. She paid him £53 odd on February 23rd, 1771, and owed about £15 when the account passed into the next ledger.

One of the folios contains "an account of what goods came in for the year 1771." From this it appears that Mr. Coyne's stock-in-trade was mainly replenished from two sources—Mr. Wilson, druggist of Chester, and Mr. Ellams, druggist of the same city. Goods to the value of £4 11s. 3d. were bought from the former, including four shillings' worth of corks and half a guinea's worth of gallipots. Mr. Ellams's account was larger—nearly £14. Phials costing £1 17s. 2d. were purchased from Mr. Seamen of Warrington, and supplies of "selter" water and other unnamed commodities came from a Mr. Hegg. On April 29th forty-seven pounds of butter were bought for a guinea!

Before concluding this note it should be mentioned, perhaps, that Mr. Coyne was very lenient in his charges to the clergy for professional services and medicines. One parson's bill, containing twenty-three items, amounted to no more than 11s. 3d., and another was charged nothing at all. Professional colleagues (Dr. Parry of Caerwys, and Mr. Blount, a neighbouring apothecary) were treated with the same consideration; sometimes a small charge was made for drugs supplied, but more often nothing. The third ledger closes sententiously with a Latin tag, written in a large copper-plate hand on the inside of the cover:

*Sic transit gloria mundi.*

Royal School, Duncannon, in 1872, when he entered Trinity College, Dublin; he obtained the second place. His college career was brilliant; he obtained a Royal Scholarship in 1872, a Classical Scholarship in 1875, and a Medical Scholarship in 1877. His professional education was conducted in the School of Physic, and the Adelphi, Rotunda, and St. Mark's Hospitals. In 1876 he graduated B.A., in 1879 M.B. and B.Ch. In 1885 he obtained the Licence of the College of Physicians, in 1886 the Membership, and in 1887 the Fellowship. He was house-surgeon to St. Mark's Hospital, medical officer to the Dublin Throat and Ear Hospital, and demonstrator of anatomy in the Carmichael College, in which he was later lecturer on pathology and medicine. In addition to his other appointments he was honorary professor of dermatology in Trinity College. Dr. Beatty was the author of several papers which he read before the Royal Academy of Medicine. These dealt with the pathology of lead poisoning, the action of mercury in diseases of the heart, and with other subjects of purely medical interest. Quite recently he published a valuable work on skin diseases. Dr. Beatty married, in 1888, a daughter of Dr. Samuel Eidge, of Granstown House, Queen's County. Of this marriage there were five sons. One, Eric, served in the Royal Dublin Fusiliers, and was killed in the war. Two other sons also served in the war—one in the Royal Dublin Fusiliers and the other in the Artillery. Another son entered the Indian Civil Service.

#### ADMINISTRATION OF THE MEDICAL CHARITIES ACTS IN COUNTY MAYO.

A subcommittee of the Castlebar District Council, appointed to consider the changes made by the Local Government Department with regard to the administration of the Medical Charities Acts on a county basis, has made a report from which the following are extracts:

We are of opinion that medical charities services should be administered by the Rural District Council, and all the appointments thereunder made by the District Council, subject to the approval of the County Board of Health. In like manner outdoor relief should be administered by the Rural District Council, and the funds for these two services should be, as heretofore, a union charge, and estimated and provided for by the Rural District Council. The making of these charges county-at-large charges is not a step, in our opinion, calculated to guarantee economy, and the administration of these services by local committees, conversant with all the local circumstances, is a guarantee that there will be proper supervision and careful spending of the funds collected from the people of the district concerned. As regards boarded-out and hired-out children's services, we also think these services should be placed with the Rural District Council. During the period the above three services—Medical Charities, Outdoor Relief, and Boarded-out and Hired-out Children—were temporarily discharged by the District Council on the abolition of the Castlebar Board of Guardians, matters were conducted with efficiency and economy, resulting in general satisfaction to the ratepaying public.

### Correspondence.

**ANTE-PARTUM HÆMORRHAGE AND ECLAMPSIA.**  
**SM.—**The letters of Dr. Johnstone (October 27th, p. 782) and of Dr. Parmore (November 10th, p. 800) raise some points of interest. As Dr. Johnstone points out, the association of eclampsia with placenta prævia, if established, supports the views on this toxæmia which I advanced in 1914. In 1921 Miller and I published a series of cases exhibiting placenta prævia with albuminuria in 37 per cent. and eclampsia in 5. The evidence is therefore strong. Placenta prævia is thus brought into line with the placental separation of accidental hæmorrhage in which toxæmia is common. The evidence of placenta prævia, moreover, throws on the problem a clearer light than has hitherto been available, for here the detachment of the placenta, to which the toxæmia is intimately related, is due to the tearing away of the placenta from its moorings by the stretching incidental to normal labour. Where the normally situated placenta is detached the toxæmia is invariably intense and often eclamptic if the placenta is retained in the womb for some time (concealed accidental hæmorrhage), whereas if the detachment is

It is established that in placenta prævia the sequence is mechanical separation, then disintegration of the placenta, then eclampsia, the argument which led me to trace the same sequence in accidental hæmorrhage gathers added volume. Albuminuria and eclampsia are, I believe, the disease of pregnancy because the large placental organ, dependent as it is on a rapidly improvised and vulnerable blood supply, is peculiarly exposed to damage and death by factors that may be purely mechanical in nature. What these factors are in the ordinary case is still matter for conjecture. That they undoubtedly operate by causing placental death is proved by finding that in a case of eclampsia (and the same applies to accidental hæmorrhage and placenta prævia), where a sufficient time elapses before labour, massive necrosis is invariably present. Where early labour takes place this necrosis is not recognizable. These findings point to the view that the poisons are produced during the early disintegration of the dying organ. I have elsewhere shown that in accidental hæmorrhage there may be indisputable evidence of venous blockage. In one such case that died of eclampsia the uterine wall supplied by the ovarian vessels on one side was in a state of acute strangulation. In the placenta the changes characteristic of necrosis were found involving nearly half the organ where it had been uplifted by the retroplacental clot. I am, etc.,  
 Edinburgh, Nov. 11th.

**CARBON MONOXIDE A PREDISPOSING CAUSE OF PULMONARY TUBERCULOSIS.**  
**SM.—**Dr. Hazleton's article (October 27th, p. 765) is of much interest to me because, as a member of the Glasgow Field Town Council, I have been endeavouring recently to draw the attention of our local authority to the danger to public health of gas leakages, especially where the monoxide content is high. In this town the percentage is 18. I am informed that in some places it is more—for example, 22 per cent. in Oldham. Maclelland is an old town, and I am well familiar with the circumstances that finally bring it to the attention of the public, both in and outside the council, feeling impelled to do this by the fact that I have had three cases in my practice this year not unknown.

If anything is clear it is that in the eclampsia both of accidental hæmorrhage and of placenta prævia there must be some common factor. There is such an obvious common factor in a mass of deritized placenta disintegrating in the womb. If it is established that in placenta prævia the sequence is mechanical separation, then disintegration of the placenta, then eclampsia, the argument which led me to trace the same sequence in accidental hæmorrhage gathers added volume. Albuminuria and eclampsia are, I believe, the disease of pregnancy because the large placental organ, dependent as it is on a rapidly improvised and vulnerable blood supply, is peculiarly exposed to damage and death by factors that may be purely mechanical in nature. What these factors are in the ordinary case is still matter for conjecture. That they undoubtedly operate by causing placental death is proved by finding that in a case of eclampsia (and the same applies to accidental hæmorrhage and placenta prævia), where a sufficient time elapses before labour, massive necrosis is invariably present. Where early labour takes place this necrosis is not recognizable. These findings point to the view that the poisons are produced during the early disintegration of the dying organ. I have elsewhere shown that in accidental hæmorrhage there may be indisputable evidence of venous blockage. In one such case that died of eclampsia the uterine wall supplied by the ovarian vessels on one side was in a state of acute strangulation. In the placenta the changes characteristic of necrosis were found involving nearly half the organ where it had been uplifted by the retroplacental clot. I am, etc.,  
 Edinburgh, Nov. 11th.

Dr. Miller has noted the same striking facts in placenta prævia, and in Dr. Bradshaw's record, which originated this correspondence, the same sequence is present. The body of facts can, I believe, be adequately explained only on the view that the poisons are generated rapidly in the deritized and disintegrating placenta and gain an immediate and easy entrance to the maternal system via the circulation of the adjacent healthy organ. Dr. Parmore challenges this view in his interesting letter with arguments to one or two of which alone space will permit me to reply. While recognizing the importance of the severity of the toxæmia in concealed accidental hæmorrhage, he thinks that the distension of the womb by the accumulating blood causes toxæmia by pressing on the kidneys and other abdominal organs. This view is disproved by the fact that there may be intense toxæmia where the concealed clot is no bigger than an apple, apart from the fact that the acute and often extreme distensions of general medical and surgical practice are never associated with eclampsia. Even if such an explanation were available in accidental hæmorrhage it is surely inapplicable to placenta prævia. Here Dr. Parmore imperfectly shelters his prejudice under the statements that "it is not surprising that multiparous woman with a placenta prævia should come to pass albumin in her urine; multiparous women are usually older than primigravidae and their kidneys cannot be expected to be as sound." The scientific insufficiency of this evidence is apparent. If anything is clear it is that in the eclampsia both of accidental hæmorrhage and of placenta prævia there must be some common factor. There is such an obvious common factor in a mass of deritized placenta disintegrating in the womb. If it is established that in placenta prævia the sequence is mechanical separation, then disintegration of the placenta, then eclampsia, the argument which led me to trace the same sequence in accidental hæmorrhage gathers added volume. Albuminuria and eclampsia are, I believe, the disease of pregnancy because the large placental organ, dependent as it is on a rapidly improvised and vulnerable blood supply, is peculiarly exposed to damage and death by factors that may be purely mechanical in nature. What these factors are in the ordinary case is still matter for conjecture. That they undoubtedly operate by causing placental death is proved by finding that in a case of eclampsia (and the same applies to accidental hæmorrhage and placenta prævia), where a sufficient time elapses before labour, massive necrosis is invariably present. Where early labour takes place this necrosis is not recognizable. These findings point to the view that the poisons are produced during the early disintegration of the dying organ. I have elsewhere shown that in accidental hæmorrhage there may be indisputable evidence of venous blockage. In one such case that died of eclampsia the uterine wall supplied by the ovarian vessels on one side was in a state of acute strangulation. In the placenta the changes characteristic of necrosis were found involving nearly half the organ where it had been uplifted by the retroplacental clot. I am, etc.,

## MELANOSIS.

THE function of pigment in the biological world appears to be similar to its function in the industrial world: it is either decorative or protective. One kind of painter adorns our drawing-rooms with works of art, whilst another preserves wood and iron work with a protective coat of coloured varnish. The delicate shades on the feathers of birds, the ingenious camouflage of certain insects, and the varied colours of the coats of other animals serve as an ornament, inciting admiration, or as a protection, acting as a warning or a disguise, or as a defence against the rays of the sun.

The pigment melanin is of great interest in human pathology because of its presence in the tumours melanoma and melanotic cancer. Mr. W. G. Spencer, in his Bradshaw Lecture on melanosis published this week (p. 907), with a large series of illustrations on a special plate, declares that there is no essential difference in the melanin which may be obtained by macerating the skin of a negro, or from the ink of a cuttlefish, or from a melanotic tumour. The pigment is formed from a colourless mother substance melanogen, which becomes oxidized to melanin. Melanogen is constantly present in the skin, as is shown by the fact that sections of dead skin slowly darken in colour, due to the formation of melanin; the same process may take place in living cells as the result of exposure to the sun or the action of chemical reagents. Melanogen is the normal precursor of melanin, and the presence of melanogen can be demonstrated in the cells of the epidermis and hair follicles of the foetus and in the embryonic cells of the retinal epithelium before any appearance of pigment. When injected into the circulation a solution of melanin appears to possess properties very similar to those of adrenaline, and Mr. Spencer is of the opinion that the pigmentation which occurs in Addison's disease, and also in dogs after the removal of the adrenals, is due to the accumulation of a mother substance common to adrenaline and melanin. The interference with the normal function of the adrenals, whereby they fail to take up this circulating mother substance and convert it into adrenaline, appears to lead to the deposition of large quantities of melanogen in the cells of the epidermis, to form melanin by oxidation.

The function of melanin, like that of other pigments, is either decorative or protective, but it is only the latter function which need concern us at present. The secretion of the ink-sac of the cuttlefish is discharged into the water to obscure the movements of the fish by colouring its surroundings. The deep brown pigment sepia may be obtained by dissolving the dried contents of the ink-sacs in dilute ammonia or soda solution, and reprecipitating with hydrochloric acid. Mr. Spencer describes the formation of this pigment in the cytoplasm of the epithelial cells lining the ink-sac of the cuttlefish, and illustrates the production of this melanin pigment. A different example of the protective properties of melanin pigment is provided by the arrangement of the granules in the ova of frogs; at first they are unpigmented, but later granules of melanin appear in the cytoplasm and serve to protect against the harmful effects of sunlight

whilst the ova are floating in the water. In the human foetus melanin pigment begins to appear in the fourth month in the epithelial cells forming the outer layer of the optic cup; in the seventh month pigmented cells are found alongside the blood vessels of the choroid which has developed from the mesoblast; the full pigmentation of the posterior layer of the iris is not complete at birth.

The pigment which is produced in the epidermis and the eyeball has a protective function and serves a useful purpose, but of what value are collections of pigmented cells in deeper structures? Probably none at all in the fully developed animal, though they may have been of value at an earlier period. Thus in the embryos of bony fish the pigment cells spread out from around the neural groove and canal in relation to the primitive body segments, and a similar explanation may account for the stripes, patches, and markings on the coats of higher animals. Such considerations have led Mr. Spencer to formulate the following hypothesis: "It seems, therefore, a rational explanation that melanin pigmented cells, whether superficial or deep, have primarily developed around the neural tube, originally for the protection of the central nervous system. The pigmented cells have spread first into the epiderm, then deeper into the mesoblast of the immediate neighbourhood, and further have been carried away in the parietal and visceral layers of mesoblast along with outgrowing nerves, especially sympathetic nerves."

The physiological formation of melanin is therefore capable of explanation, but the pathological production of this pigment is shrouded in the mists which obscure the development of all new growths. We know of certain agents which are capable of oxidizing the melanogen normally present, and which accordingly appear to increase melanin pigmentation. The black spots which follow the bites of the body louse, the pigmentation which is produced by excess of arsenic, the development of freckles after exposure to the sun, appear to belong to this category. In certain disorders of the endocrine glands increased pigmentation may occur, and an explanation has already been offered for the darkening of the skin which occurs in Addison's disease, by assuming that melanogen is deposited in the epidermis instead of being converted by the kidneys into adrenaline. A curious example of the "banking up" of melanin pigment is provided by the tumours so frequently appearing in grey horses, which in old age tend to become white through the loss of pigmented hair. No change takes place in the unpigmented skin, but any area, such as the ano-genital region, of normally pigmented skin is likely to become the site of a melanotic tumour.

The insidious change whereby a congenital melanoma assumes the character of a melanotic cancer remains a mystery, but research has shown that migration of branched pigmented cells may precede any sign of cancer. Wounds of the skin which have resulted in a small pigmented area may after years of quiescence suddenly assume the character of a malignant melanotic growth.

Variations in the amount of pigment in the eye are very frequent. The name "wall eye" is applied to a condition observed, particularly in the horse, in which there is a large amount of white showing, or where there is absence of colour in the iris or a dense opacity of the cornea. The expression, it may be noted in passing, is derived from the Icelandic word for a beam or sty in the eye. But such variations in pigment rarely lead to melanotic cancer. When such

malignant disease does occur in the eye it generally arises from the pigmented layers within the eyeball, and develops as a rule after middle life.

The occurrence of melanotic cancer in other regions of the body—such as the hard palate, the abdomen, the ano-genital region, and the pia mater of the brain and spinal cord—is difficult to account for. It is easy to find a satisfactory explanation for the physiological development of melanin pigmentation; it appears in obedience to definite laws and serves a useful purpose. We are in complete ignorance of the laws which govern the pathological development of this pigment in melanotic cancer. Vague hints and slender clues may be furnished by a study of comparative pathology, and these are worth pursuing. But the uselessness of tumour growths is their most baffling property, for, just as crime is most difficult to detect when there is no apparent motive, so morbid processes are most difficult to understand when they have no obvious object.

### THE INSURANCE CRISIS: THE DECISION.

THE special Conference of Representatives of Local Medical and Panel Committees, called by the Insurance Acts Committee to consider the Minister of Health's revised offer, was held on Wednesday, November 14th. It will be remembered that the Minister's offer, conveyed in a letter published in the SUPPLEMENT of November 3rd (p. 209), contained certain declarations and two alternative proposals. Sir William Joynson-Hicks declared in the first place that medical benefit is a primary benefit and that there is no title to additional benefits until this and the other primary benefits—sickness, disablement, and maternity—are provided. In the second place he declared that the remuneration of practitioners is a matter to be considered on its merits and agreed by negotiations between the Minister and the profession. In regard to the immediate question of remuneration the Minister offered, alternatively, a guaranteed fee of 8s. 6d. for five years, or a separate and immediate inquiry into the appropriate capitation fee for 1924.

At the reassembling of Parliament on November 13th several questions on this subject were put to the Minister of Health, who in his replies indicated that a fuller statement from him might be expected on Thursday after the decision of the Panel Conference. In the meantime he informed the House of Commons that if the offer he had made was accepted by the Conference he proposed to lay on the table a White Paper on the whole subject, which would include an actuarial report. Upon this Sir Ryland Adkins asked, "Is it an agreement assented to by the Approved Societies?" To this the Minister made the following significant answer: "No, sir. I, as Minister of Health, after fully considering the whole matter, have made alternative proposals to the doctors. If either of these proposals is accepted legislation will be necessary, and I hope to have the responsibility of bringing in that legislation and submitting it to the House."

The Panel Conference, having "heard great argument about it and about," resolved by 141 votes to 29 to accept the Minister of Health's offer. The Conference then discussed the advantages and disadvantages of the Minister's two alternatives *a* and *b* embodied in his offer. After close debate, revealing differences of opinion, alternative *b* was accepted by 123 votes to 49. A motion to accept the Minister's offer, including alternative *b*, was then put to the meeting as a substantive resolution and carried unani-

mously. The result of the Conference is therefore the acceptance on behalf of insurance practitioners of a special Court of Inquiry to be set up by the Minister as soon as possible and instructed to report on the capitation fee to be paid as from January 1st next. The contract will be made on the basis of the fee recommended by the Court of Inquiry, the Government undertaking to go to Parliament for the necessary legislative sanction and the profession undertaking to accept the recommendation.

### THE BRADSHAW LECTURES.

THE Bradshaw Lectures at the two Royal Colleges in London were delivered this year at the Royal College of Physicians by Dr. John Hay, physician to the Royal Infirmary, Liverpool, on November 1st, and by Mr. W. G. Spencer, surgeon to the Westminster Hospital, at the Royal College of Surgeons; the latter lecture is published this week (p. 907), and we hope to give some account of Dr. Hay's lecture, which was concerned with the prognosis of angina pectoris, in an early issue. The lectures were founded by his widow in 1880 in memory of William Woods Bradshaw (1801-66), who became a member of the Royal College of Surgeons of England and Doctor of Medicine of Erlangen in 1833, a Fellow of the Royal College of Surgeons in 1854, an extra-Licentiate of the Royal College of Physicians in 1841, and a member in 1859. In the Bradshaw Lecture for 1910 (vide BRITISH MEDICAL JOURNAL, December 10th, 1910) at the Royal College of Physicians, Dr. Newton Pitt, in giving some details and a photograph of Dr. Bradshaw, mentions that at the mature age of 43 years he matriculated at Newton Hall, Oxford, and was granted a degree without examination. He was an M.D. and D.C.L. of that university, and is described as "a cultivated, refined, and somewhat eccentric man with a rather theatrical manner who never did much practice." His wife was the widow of a wealthy jeweller at Andover, whose money was to be forfeited in the event of remarriage, but after purchasing the reversion she and Dr. Bradshaw married and settled down at Reading. As originally directed the lectures were to be given on the anniversary of Dr. Bradshaw's death, August 18th, but in 1891 the sanction of the Charity Commissioners was obtained to depart from this date. These annual lectures were given for the first time in 1881, and at the Royal College of Physicians the late Dr. Vivian Poore took for his subject "The nervous affections of the hand"; other lectures notable for bringing new information to the notice of the profession were the late Professor W. S. Greenfield's "On some diseases of the thyroid gland" (1893), which gave the first full account of the histological lesions of the gland in exophthalmic goitre, and Sir Thomas Barlow's "Infantile scurvy and its relation to rickets," the completeness of the description being responsible for the name "Barlow's disease," a term perhaps less familiar in this than in other countries. It may also be noted that exophthalmic goitre formed the subject-matter of the two other Bradshaw Lectures at the same College by Professor George Murray in 1905 and by Sir Hector Mackenzie in 1916.

### PSYCHIATRIC PROBLEMS OF THE FUTURE.

AN address which touched on many subjects and gave to each of them a philosophical significance was delivered to the Section of Psychiatry of the Royal Society of Medicine on November 13th by the new president, Dr. T. B. Hyslop. He traced the progress of psychology since his presidency of the Section of Psychological Medicine at the British Medical Association meeting in London in 1910. During the intervening years the civilized portion of the globe had undergone such a violent upheaval that the thoughts of every person must have been drawn to the question

There is only one consideration that I wish Sir William

had added to his excellent summing up of the situation, and that is this: in almost every instance, where we are dealing with the severe ("Asiatic") type of the disease, the cases which will be found to be mild modified cases in once-racinated subjects whose vaccination has "lapsed." Had these cases been unvaccinated the attack would have been much more severe and their nature much more obvious, and almost certainly they would not have been overlooked. I am convinced that sufficient importance has not hitherto been attached to this consideration. I agree with Hewlett and Xanthrell when they say:

"Given that the staff of the health department is sufficient and that the provision of hospitals . . . is adequate, the control of small-pox is more easy among one that is partially unvaccinated."—*Principles of Preventive Medicine*, p. 356.

They go on to recommend universal revaccination as the ideal, but if we cannot have universal revaccination it looks as if our present system was worse than useless!

It is not surprising that the present ultra-mild American type of small-pox is proving so difficult to deal with in view of the cases with which the disease is overlooked. Fortunately, however, the mildness appears to be inherent and breeds true, so little injury to health is caused. Indeed, it is very possible that we shall come to regard it as a "para"-small-pox. But if this is so we are clearly not justified in using the horrors of the old severe Asiatic type of small-pox as an argument for insisting upon the necessity for universal infant vaccination as a protection against the new ultra-mild American small-pox.—I am, etc.,

C. KUTLER MILDARD.

\* We refer elsewhere to Dr. Millard's letter.

## ATTITUDE IN CATHERIZATION OF THE BLADDER.

SM.—Why is it so easy for a bladder to get infected from catheterization of a patient in bed in spite of most scrupulous aseptic and antiseptic precautions, and yet one so often meets or hears of patients who have been in the habit of passing a catheter on themselves for many years without any marked signs of cystitis? May it not be due to drainage of the bladder, in the latter case from its most dependent part, and in the former case from a point which is not its lowest part? Most patients who pass the catheter for themselves do so either standing or sitting up; but they are in the prone position when the catheter is passed on them.—I am, etc.,

H. E. BAYBEN.

## ASTHMA DUE TO INSECT POWDER.

SM.—The answers to the two questions asked by Dr. Coke (November 3rd, p. 841) are as follows: (1) The patient's sensitiveness to dog hair was not tested, since she had frequently been closely associated with dogs, but asthma had only resulted from a combination of dogs and insect powder. (2) The powder was tested on a normal arm with a completely negative result.—We are, etc.,

J. R. GAVANITY,  
Joseph W. Bigger.

Dublin, Nov. 10th.

## BUTYR AS A LOCAL ANAESTHETIC.

SM.—As an addendum to Dr. William Hall's notes on butyr (November 10th, p. 876) it should be stated that this substance cannot be used exactly as cocaine. Quite a small quantity of the solid laid on a dry produced white sloughing of the conjunctival surface, and violent chemosis followed, although it was washed off in a few seconds. Considerable care should therefore be exercised in the use of the strong solutions, and the solid regarded as a possible escharotic for mucous surfaces, causing violent inflammation in some cases.—I am, etc.,

London, W., Nov. 10th.

JAMES KERR.

SM.—The article by Dr. William Hall (November 10th, p. 876) coincides in every way with my experience of butyr. I was unable to procure, in time, a supply of the anaes-

thetic to do justice to the preparation, so withheld the answer to the inquiry of the Cocaine Substitutes Committee of the Ministry of Health. On a series of minor operations on the nose and throat I have found butyr inferior to cocaine; striking examples being on the same patients in whom both sides of the nose required interference to practically equal degrees, using on one side cocaine, and on the other butyr 5 per cent. The comparative comfort and discomfort in certain cases was very evident, the patients in these cases volunteering the statement that in one case the discomfort was much greater. Of course, the anaesthetic was not divulged to the patient. In eye operations butyr is very satisfactory as an anaesthetic, but there are two disadvantages: excessive smarting, on first application, and hyperaemia of the conjunctiva, especially in certain individuals. I hold that cocaine is still dominant in eye, throat, and nose operations.—I am, etc.,

ALFRED FENCOTSON, F.R.C.S.E.D.,  
Surgeon to Diseases of the Eye, Throat, Nose, and Ear to the Jersey General Hospital.

## PAY OF MARRIED I.M.S. OFFICERS.

SM.—I have read with interest recent letters from officers of the R.A.M.C., and venture to make similar remarks regarding the pay and allowances of married officers of the sister service to which I belong. Married officers in the Indian Medical Service, in common with all married officers in other branches of the service in India, receive no married allowances, but identical the same pay and allowances as unmarried officers. Their expenses are not less than double, and in the case of married officers with families more than treble, those of unmarried officers. They are obliged to keep up two establishments for six months in every year when their wives and families are forced to go to the hills on account of the prejudicial effect of the climate in the plains during the hot weather. The move to the hills and back is alone sufficient to cause great anxiety; the rents of houses are exorbitant, food and necessities excessive in price, and servants demand enormous wages. All this is well known to the Government of India, which has, up to the present, done nothing to alleviate the sufferings of married officers. India is becoming day by day a country in which a married European officer cannot hope to live with any self-respect, as he is expected to give the best years of his life towards serving a Government which will not realize that he must necessarily be in a constant state of anxiety regarding the present and the future of his family and himself.—I am, etc.,

MAJOR I.M.S. (RETIRED).

October 21st.

## Universities and Colleges.

AT A CONGREGATION held on November 9th the following medical degrees were conferred:  
M.B., B.Ch.—L. B. HARTLEY, R. C. HEWITT.  
B.Ch.—L. M. THOMAS (admitted by proxy).

## UNIVERSITY OF LONDON.

At a meeting of the Senate held on October 24th Mr. Geoffrey E. DUEEN's offer of £10,000 for the establishment of a University Lectureship in oculo-gy was accepted and the thanks of the Senate were accorded to the donor for his generous gift. It was reported that Mr. DUEEN had suggested that the first holder of the lectureship should be Mr. Richard LAKE, F.R.C.S., surgeon to the ear, nose, and throat department of University College Hospital. The Academic Council reported that Professor F. W. COLTONS had intimated his inability to accept the University professorship of anatomy, renewable at St. Bartholomew's Hospital, to which he was appointed in May last. It was decided for the second examination for medical degrees, Part I, in March, 1924, the syllabus in force in 1923 be adopted; and that in and after 1924 the M.B., B.S. examination be held in November-December for internal and external students be held in November-December instead of October. Mr. H. J. WATKINS has been elected chairman for 1923-24 of the Royal Animal Sanitary Institution Committee. The M.D. examination for internal and external students, July, 1923, has been awarded to P. C. P. CLOKE (London Hospital), and the M.D. examination for Branch III (psychological medicine) of the University in Branch III (psychological medicine) of the University College Hospital).

whither humanity tended. Evolution and devolution were constant throughout the universe, but the human mind curiously claimed exemption for itself from the process of devolution. Men noted, with complacency the rise and fall of nations and civilizations, knew that worlds were born and died, and in their rational selves were aware that this world must conform to its allotted destiny; yet we were blind to its ultimate devolution. The philosophical conclusion arrived at from the data of physics and psychology was that mind in its ultimate essence was coextensive with energy. From Myers's doctrine of the subliminal self there had followed a flood of conjectures, some of which appeared to be legitimate. Sir Oliver Lodge endorsed the view that the individual was but an incomplete fraction of a larger self, a portion only of the whole self, which was in intimate contact with matter. Dr. Hyslop agreed with the view that in the association of spirit with matter the incarnation of something pre-existent appeared to be a reality, and that the gradual utilization of matter by pre-existing life or spirit might really occur. He asked that in dealing with such problems a greater measure of tolerance should be shown. He next dealt with the attempts which had been made to localize mental states to certain physical areas; these attempts had not so far had much success. By destroying or severing the connexions of any of the cortical areas existing activities might be cut off or the results of former activities rendered inert, but beyond that it was not possible to go. With further advances in knowledge of the data of consciousness and of brain structure there might be formed some definite doctrine of cerebral localization, but the answer of cerebral anatomy and physiology to the question of the localization of consciousness had been of little value hitherto. The activity of the sense organs was undoubtedly determined originally by cosmical means outside the body, but those means had to be changed and modified before they could determine consciousness. Even though the ideal elements of science were reached there would still be no explanation of how the physical organism enveloped specific forms of motion upon which consciousness was superimposed. The nerve cell, in his view, consisted of two distinct elements, one neuroplasmic and the other trophoplasmic. He saw in each nerve cell nothing else than modifications of the neuroplasmic fibrillae and the trophoplasmic adjuncts. Each cell was but a station or junction where the neuroplasmic fibrillae were structurally continuous and had for their common use a comparatively large trophoplasmic process. The long discussion as to the individuality of the neuron lost its difficulty to a great extent when these two factors were considered—a continuous neuroplasm, and a trophoplasm which was contiguous, and acted through its relations to the neuroplasm or its dependence on biochemical or other influences from without. The neuron theory had never been adequate, and it ought to be supplemented by the trophon theory. The trophon was to all intents and purposes a structural and functional equivalent to a pulsatory lymphatic heart, deriving its activities and energies from chemico-physical changes within the neuroplasm. The trophons were probably during life subjected to pressure due to various causes, including mechanical. It was reasonable to conjecture that mental abnormalities were due to the disruption or short-circuiting of currents in nerve tracts originating in either the trophon or the neuron. Dr. Hyslop held to the view that the nervous system was a mechanism for the transmission of force, and not a generator of force. The nerve fibrillae were purely conductors in function. The nerve cell or the trophon did not initiate energy, but simply supported, protected, and nourished the fibrillae. The progress of psychiatry had been slow and laboured.

It was not to be compared with the progress of surgery and certain departments of medicine. But the methods of Freud and his disciples had during the last few years led in some instances to a more thorough understanding of various mental states. The study of the physiology of the nervous system had shown the value of the experimental destruction or excitation of the accessible microscopical parts, but the anatomical facts, instead of elucidating the problems of the physical basis of mental processes, had tended rather to increase the difficulty of understanding the complex mechanism of the nervous system. Science and religion were coming more and more into accord as the knowledge of realities became more manifest, and it was not out of the question to think that a creative and an emergent evolution might be shown to be in complete agreement. Science needed the background of eternity.

#### CANCER CURERS.

THERE are in most big towns persons who profess to be able to cure cancer by drugs to be taken internally, or by local applications—"without the knife," as the saying is—but it is probably in rural districts and in their small market towns that the curers by lotions, ointments, and plasters most flourish. They do much harm; they are the cause of great suffering, physical and mental, but their practice is not illegal, and while they avoid certain obvious pitfalls they can continue so long as the local public is willing to believe their promises. Occasionally, however, they are not sufficiently astute to avoid the long arm of the law. A case heard recently in the Doncaster County Court before His Honour Judge R. W. Turner presents certain features, particularly the terms of letters written by the defendant, which are worthy of note. The following account is founded upon reports in the *Yorkshire Herald* and the *Yorkshire Post*. The case came on first on October 24th; the plaintiff, the wife of a labourer in the village of Bentley, sued the defendant for the return of £11 paid to him for the cure of cancer, which had not been carried out. The defendant issued a circular in the form of a letter in the course of which he said, "I am willing and prepared to accept any cancer case and to cure them thoroughly without any operation whatever. . . . After I prove my abilities I will sell my remedy to any medical gentleman or physician for a reasonable sum or stand in with them. . . . No cure no pay." The case was adjourned to enable the claim to be amended. At the second hearing, on November 7th, the claim was for the return of £11 fees for the treatment of cancer, damages for breach of warranty, and damages (£50) for pain and suffering. The plaintiff, who had been a patient of Dr. Ashurst of Bentley, was found by him to be suffering from a tumour which was not cancerous. He recommended her to go to the Sheffield Infirmary; she was there offered admission with a view to operation, but refused. She then went to see the defendant. He was not at home, but afterwards wrote her a letter, dated June 23rd, as follows:

Dear Madam,—Guaranteed. Call about 12.30 p.m. Sorry I was not at home this evening on your calling. To speak candid I am scarcely at home, always on the prowl or detained. Some persons want me. But nevertheless as a servant of the Most High God. The blessing that He as bestowed upon me more than mankind I only wish all blessings to go to my God of the Heavens. If you can pay me each week for the drugs that you require to destroy all the roots, the fangers, and to draw the cancer cord away, I will cure your bosom, chest, and system and make a sound cure of you; then give me for my trouble what you can afford and oblige.—Yours obediently,

David Williams.

On June 28th the defendant called and examined the plaintiff, and told her that she was suffering from cancer, but he could cure her in a month or six weeks; she agreed to pay him £2 a week. He supplied her with a lotion, a green ointment, which brought on boils and blisters, and

JAMES H. HARRIS

also put on a plaster. During this treatment she suffered much pain. Mr. John Adams, public analyst, Sheffield, said that the lotion was partly ammonia; the ointment blue vitriol, sugar of lead, and bread; and the plaster mainly tar. For the defence it was urged that the defendant had used a method described in John Wesley's *Common-sense Medicine for Common-sense People*. When the judge remarked that science had advanced since then, the reply was that the method was a resuscitation of an old-world remedy for cancer, and that evidence of some success could be produced. The judge did not accept this statement, observing that the evidence at present was that there is no cure for cancer. In giving judgement the judge said that the defendant had had the money and must return it to satisfy the terms of his advertisement, "No cure no pay." These classes of people, he went on, were always talking of their alleged successes, and there was a class of people who always believed them. The judge entered a verdict for the return of the £11, with £30 for pain and suffering. The judge said that the case was important to the public, and gave costs on Scale C, with qualifying fees for the analyst and the doctor. The judge's observations were so much to the point that it does not seem necessary for us to add anything by way of comment.

#### WINTER SPORTS IN FRANCE.

Few people associate the Riviera with snow and winter sports, but in the article on wintering on the French Riviera published a year ago (October 28th, 1922, p. 815)—an article which deservedly attracted much attention and has been helpful to many, both would-be visitors and their medical advisers—it was pointed out that there were many places in the Alpes Maritimes where a true mountain climate could be reached within an easy journey of the Mediterranean. The writer of that article had in mind chiefly the use of such places to escape the summer heats, but we learn from a leaflet on winter sports in France that one place at least in that district is laying itself out to attract winter snow-lovers. This is Peira-Cava, at an elevation of 4,757 feet, within 40 kilometres of Nice, from which it can be reached by motor omnibus. The French are, in fact, showing a great deal of enterprise in establishing winter sports stations. The two highest are in the Pyrenees—Font-Romen and Luchon-Superbagnères; both, curiously enough, are 5,906 feet high, and at both new and well appointed hotels have been built. Font-Romen is in the Eastern Pyrenees and is surrounded by forests; it can be reached from Paris in thirteen hours. Bagnères-de-Luchon in the Central Pyrenees (fifteen hours from Paris) is a well known summer watering place with thermal sulphur springs, at a height of 2,066 feet; Superbagnères stands in an open situation 3,840 higher up; it is reached by a funicular railway in about an hour. In addition to the large new hotel there, every class of hotel is to be found at Bagnères-de-Luchon itself. Cautelets, also in the Pyrenees, hitherto known as a summer resort, is now seeking to attract the winter visitor also; it has the advantage of presenting a considerable choice in hotels, but it is only 3,363 feet high, which some will think not high enough. The jumping-off place is Pau. St. Pierre de Chartreuse, a village on the road from Grenoble to the monastery, is described as a quiet place having arrangements for sports; it is 3,117 feet above sea-level. Another high-lying place in quite a different district is Mont Revard, at an elevation of 5,068 feet; it is eighty-five minutes by a mountain railway from Aix-les-Bains, of which it seems to be looked upon as an annexe, but it has a small hotel of its own. Mégeve (3,750 feet) in Savoy is said to be especially good for ski-ing, and there is always Chamonix (3,409 feet), where the winter sports section of the eighth Olympic Games is

to be held this winter, when the annual international ski-ing competition organized by the French Alpine Club will take place for the French challenge cup. Full information about all the places mentioned and how to get to them can be had from the Office Français du Tourisme, 56, Haymarket, London, S.W.1.

#### VACCINATION PROPAGANDA.

WE publish elsewhere in this issue a letter from Dr. Killick Millard with reference to the editorial article entitled "Vaccination propaganda" in our issue of November 3rd (p. 826). Dr. Millard accepts our correction of his error as to 165 deaths attributed to vaccinia; but as to his other erroneous statement with regard to the conscience clause he makes a defence of which he gave no hint in what he wrote in the JOURNAL of September 29th (p. 564). He there spoke of the conscience clause "proposed as a result of the Royal Commission's report"; he was therefore referring to the clause of the Act of 1893, not to the altered clause in the Act of 1907. In his letter published this week he introduces fresh matter. By his quotation from Sir William Hamer's report he shows that he appreciates the great value of the Ricketts-Wanklyn method of diagnosis for the prevention of epidemics; but he goes on to say that he is convinced that further aid in dealing with small-pox of the old type would be obtained by refraining from the practice of infant vaccination, because then an attack of small-pox would be more severe and therefore more easily diagnosed. "Had these cases," he writes, "been unvaccinated the attack would have been much more severe and their nature much more obvious, and almost certainly they would not have been overlooked." Such severity would of course be attended by more pitting of the skin in the event of recovery, and by a higher mortality among persons attacked. The vicarious beneficiaries would be the children of parents who in no case would have had them vaccinated, either through mere neglect or through disbelief in vaccination. In short, certain children are to be immolated on the altar of diagnosis in order to protect other children whose parents refuse to give them the protection of vaccination. It is apparently for their sake that those who would otherwise have been submitted to vaccination are to be left unprotected. The sympathy of everyone will be with the bereaved parents of infants who have been infected with sepsis or erysipelas after vaccination, however the infection may have been brought about. But are we to have no sympathy with the proposed victims of easier diagnosis? On the one hand, erysipelas is a rare sequel to a measure of the greatest protective value. On the other, severe small-pox might be the result of omitting to bring influence to bear in support of the protective operation.

#### AGGLUTINATION OF DIPHTHERIA BACILLI.

THE Ministry of Health has issued a paper<sup>1</sup> by Dr. W. M. Scott on the agglutination reaction of diphtheria bacilli. It is a contribution to practical questions concerning the carrier problem and to the discrimination between pathogenic and non-pathogenic types of the bacillus. These types are indistinguishable by cultural and morphological tests; Dr. Scott set out to determine whether they could be distinguished by their serological behaviour. In studying 265 strains he found eight main serological groups, but there was evidence of other groups not identified. Six of these groups contained only toxigenic strains, while the remaining two included toxigenic and non-toxigenic cultures. The unidentified strains and also the non-virulent (but otherwise typical) strains were much commoner amongst contacts and carriers than amongst

<sup>1</sup> It forms part of No. 22 Reports on Public Health and Medical Subjects. Issued by the Ministry of Health. H.M. Stationery Office (2s.) or through any bookseller.

Other pieces of popular writing were the address which he delivered as president of the health section of the Social Congress at Huddersfield in 1883, on "Hurry, worry, and money—the bane of modern education"; a pamphlet on the economy of coal in house fires published in 1866; and a lecture on the principles of domestic fireplace construction, delivered at the Royal Institution in 1886. The titles of these are sufficient clue to their subject-matter. He was elected a Fellow of the Royal Society in 1888 and was Honorary D.Sc. Leeds in 1904. He was a Crown Representative on the General Medical Council from 1876 to 1901. He married first, Alice, daughter of the Rev. W. H. Teale; she died in 1891; and secondly, Jeannette daughter of D. C. Jones, Esq., of Tammworth. He leaves four sons and four daughters. One of the sons carries the medical inheritance of the family into the fourth generation.

DAVID W. FINLAY, B.A., M.D., LL.D., F.R.C.P., Emeritus Professor of Medicine in the University of Aberdeen.

Dr. David WHITE FINLAY, whose death at "Balgownie," Helmsburgh, on November 15th, we regret to record, was Regius Professor of the Practice of Medicine at the University of Aberdeen for over twenty-one years.

He was born in Glasgow eighty-three years ago, and was educated at Glasgow High School and Glasgow University, where he graduated B.A. in 1860 and M.D. (with commendation) in 1864. He took the D.P.H. of Cambridge in 1883, and was elected F.R.C.P. Lond. in 1885. He also studied for a time in Vienna. For some years he held the appointment of physician to the M.A. Hospital, and was lecturer on clinical medicine, forensic medicine, and public health in the medical school. He was also physician and afterwards consulting physician to the Royal Hospital for Diseases of the Chest in London. In 1891 he was appointed Regius Professor of the Practice of Medicine in the University of Aberdeen, and physician to the Aberdeen Royal Infirmary. When in 1912 he retired from the chair he became Emeritus Professor, and the University afterwards conferred upon him the honorary degree of LL.D. He took a keen interest in the affairs of the University, and in 1900 he represented it at the bi-centenary celebrations of Yale University, where he received the honorary degree of LL.D. In 1908 King Edward VII appointed him one of his honorary physicians in Scotland, and in 1911 King George V conferred a similar honour upon him. He was the representative of the University of Aberdeen on the General Medical Council from 1901 to 1911. He contributed many articles to the medical journals and to the transactions of medical societies, and he was the author of the article on pneumothorax in *Albion's System of Medicine*. During the war he held the rank of temporary lieutenant-colonel R.A.M.C., and was in charge of the Scottish National Red Cross Hospital at Bellahouston, Glasgow.

His chief recreation was yachting, on which he was a recognized authority, and he published several works on the subject, including, in 1910, *Memoriscences of Yacht Racing and Some Racing Yachts*. He was a member of the first council of the Yacht-Racing Association and of the Royal Clyde Yacht Club and other yacht clubs. He married a daughter of the late Mr. Stephen Thompson, shipowner, of London, and had two sons and four daughters. We are indebted to Dr. ASHLEY MACINTOSH, the present Regius Professor of Medicine in the University of Aberdeen, for responding to our request for a tribute to Professor Finlay's memory, as follows:

I shall always be glad and proud to think that I was a pupil and, later, a colleague of Professor Finlay. When he was appointed Regius Professor of Medicine at Aberdeen in 1891, it was felt to be no little gain to have secured a man who was a graduate of another Scottish university and had already gained considerable experience of medical practice and teaching in a great London medical school. And the result justified the expectation.

As a teacher he was eminently careful, lucid, and direct. His systematic lectures were illustrated and amplified by a series of excellent lantern slides. In his clinical teaching

he followed largely the Socratic method of question and answer, and his students quickly learned that a straight question demanded a straight answer—nothing else would satisfy our teacher. By example, as well as by precept, he taught the necessity of following Sydenham's "method" of careful, close, continued observation of diseases. He insisted on accuracy—"the old Hippocratic dictum"—in his students as in himself; he could tolerate almost anything rather than slipshod work. And if, at times, interest did appear to be sacrificed to detail, this was surely a fault in the right direction in a teacher. Through all his work he had the saving grace of quiet, dry humour, and his students knew that he took a keen and living interest in them and their welfare. He was a loyal supporter of the movement to secure a better arrangement of hours for clinical study at the infirmary. I can testify that his interest in his old students and in the university generally was fully maintained up to the end of his life.

As a man and friend, Professor Finlay was loyal, down-right, and sincere; he did his work and said his say without fear or favour. When he retired in 1912, Aberdeen University lost a distinguished professor and teacher, a sound and wise counsellor. His death will leave in the hearts of his former pupils and other attached friends a sense of very real loss. I can never forget his unflinching kindness, thoughtfulness, and courtesy, and how very much I owe to him.

We are glad also to be privileged to publish this eloquent note on Professor Finlay's sterling qualities as a man: "And by and by, they gang awa," as George MacDonald has it in his beautiful line, and the medical profession is the poorer by the passing of David Finlay, a true Scot, a man of sterling worth, and a steadfast friend. One of the old school, he had all the courtesy and repose of the Victorian— a noticeable and pleasing feature in these hectic Georgian days. Upright and honest to a fault; a hater of sly, sham, and shoddy; ever imbued with a high sense of duty; constant to the task in hand; meticulous in detail, and somewhat impatient of the working of minds less well ordered than his own; a man of firm determination, and to some extent a man of firm determination, and to some human kindness and endowed with a keen sense of humour—such was "David," as he was affectionately called by a generation of students. To his sterling work at Marischal College and in his wards at the Royal Infirmary, a competent authority will bear testimony. As Emeritus Professor he continued to take an active interest in the Aberdeen Medical School, and on leaving the Royal Infirmary he presented a large number of medical books and periodicals as a reference library for the resident staff. From the Silver City by the Sea he went to Glasgow, and thence to Helmsburgh, where from his house of Balgownie a name redolent with memories of Aberdeen—he could look out upon the well-known waters of the Firth of Clyde, for he had ever felt the fascination of "the many-sounding sea," and on the title-page of his interesting book, *Reminiscences of Yacht Racing*, had inscribed Byron's lines, which might well have been written of himself:

"And I have loved thee, Ocean! and my joy  
Or youthful sports was on thy breast to be  
Born, like thy bubbles, onward: from a boy  
I wanted I with thy breakers—they to me  
Were a delight."

He and his brothers from their youth upwards had been fond of boating, and had owned and raced many yachts on the home waters of the Clyde and elsewhere. One of these, the *Albion*—a prominent picture on his study wall—was described by an authority as "by far the best boat of her more sober, but still pre-eminently satisfying and healthy" excitements and striving "of racing gave place to "the power the best craft that life ever turned out." When the "excitements and striving" of racing gave place to "the more sober, but still pre-eminently satisfying and healthy" getting pleasures of cruising," he sailed his yacht among the Western Isles, and wrote eloquently of the beauties of Skye, Mull and Morven, and of the cliffs of Rum and Skye, and remained with him an imperishable memory. Scenae which appeared strongly to his sense of the picturesque, and remained with him an imperishable memory. Scenae were his favourite pictures, and of these he had many, while enlarged photographs of white-winged gulls sailing on waters harked by Higland hills covered the

convalescents and acute cases. The non-toxicogenic strains which conformed to the ordinary microscopic and cultural standards of *Bacillus diphtheriae* were also found to respond to the serological tests of virulent bacteria proving membership of this species; but this was not the case with the strains which are commonly described as "atypical diphtheroids," a fact which provides further evidence that such strains are not true diphtheria bacilli. A study of the relationship of different antigenic types of diphtheria bacilli to different epidemics showed evidence of association of particular epidemics of diphtheria with particular serological groups of the bacillus.

#### FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

THE fifth congress of the Far Eastern Association of Tropical Medicine was held in September at Singapore, and was attended by over 300 medical practitioners, representing fifteen countries. The president of the congress was the Hon. Dr. A. L. Hoops, principal civil medical officer, Straits Settlements. The association was founded in 1908, when a small gathering of medical men met at Manila, and the first congress was held in the same city in 1910. The second congress was held at Hong-Kong in 1912, and the third congress at Saigon in 1913. The war caused a lapse of eight years, and the fourth congress was held in 1921 at Weltevreden in Java. It is intended to hold the next congress two years hence in Tokio, at the invitation of the Japanese Government. In his presidential address Dr. Hoops gave a brief survey of the work that had been done in the last twenty-five years in tropical medicine, and indicated the directions in which further work was still necessary. He said that for the widespread practice of preventive medicine an educated public, co-operating with educated medical officers, was required, and the mainstay of prevention in rural districts must be the rural practitioner. He insisted that there was nothing inherently unhealthy in a tropical climate, and there was no reason why the figures of the death rate and infant mortality rate in England should not be approached in the tropics.

#### WOMEN'S MEDICAL SERVICE FOR INDIA.

THE Council of the Countess of Dufferin's Fund has issued its thirty-eighth annual report on the work of the National Association for supplying medical aid to women in India. The publication includes the ninth annual report of the Women's Medical Service for India. At the beginning of 1922 this service consisted of 38 medical officers with 4 temporary officers. The number of women medical students was 436, and there were altogether 400 women practitioners of medicine in India, as many as 145 hospitals being staffed by women alone. These figures indicate the great advances which have been made in providing medical aid by women since 1885, when the Dufferin Fund was formed. Large areas are, however, still unprovided with medical relief by women. Statistics compiled by the public health departments of the various provinces show a large excess of deaths among women at the child-bearing age, pointing to a high mortality at the time of childbirth. Moreover, infant mortality in India is still excessively high. The Council of the Fund thus summarizes the chief needs of the country as regards medical aid by women: (1) A far greater number of hospitals staffed by women; (2) a far larger supply of Indian women doctors both for hospital and private work; (3) more opportunity of post-graduate work to keep up the standard of professional knowledge; (4) training schools for nurses and midwives in connexion with every women's hospital; (5) more funds for the working of the hospitals in order that thorough and efficient work may be carried on; (6) a constant supply of

women doctors, nurses, and midwives to take up preventive work in connexion with maternity and child welfare in all parts of the country.

THE first David Lloyd Roberts Lecture will be delivered at the Royal College of Physicians of London on Tuesday, November 20th, at 5 p.m., by Mr. Edmund Gosse, C.B., LL.D. The subject of the lecture is "Personal relations between medicine and literature."

SIR WILLIAM MACEWEN was the guest of the California Academy of Medicine, San Francisco, on September 20th, on his way to Australia as representative of the British Medical Association at the Australasian Medical Congress. He addressed an assembly of about 150 medical practitioners, among whom was Dr. Ray Lyman Wilbur, president of the American Medical Association.

ON Thursday, November 29th, at 5.30 p.m., Sir W. J. Collins, M.D., will give a lecture at University College, London, on the life and doctrine of Sir Edwin Chadwick. Tickets of admission can be obtained on application to the Secretary of the College.

SIR DONALD MACALISTER, K.C.B., Principal of the University of Glasgow and President of the General Medical Council, has been appointed a Deputy Lieutenant of the city of Glasgow.

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

#### The General Election.

ON the reassembling of the House of Commons on November 13th, Mr. Baldwin announced that he had decided to advise His Majesty to dissolve Parliament on Friday, November 16th, which means that a general election will take place on Thursday, December 6th. He explained that this resolve was taken on account of the grave problems of unemployment, and because he had reached certain conclusions he could not act upon unless he were relieved of the pledge given by Mr. Bonar Law as affecting the present Parliament. He thought that as in these circumstances a general election was necessary, it should take place at the earliest possible time. Hence the choice of date.

It is hoped that the new House will meet on December 10th for the swearing-in of new members, and after two or three days will adjourn until the end of January, when the business of a new session will begin.

The Government majority over all other parties in the House of Commons at the present time is 73. One result of the declaration of fresh policy by Mr. Baldwin is that the two wings of the Liberal party have come to an agreement to work together.

#### The Panel System.

Sir Kingsley Wood asked the Minister of Health on November 13th whether he could state the present position of the negotiations with the doctors on the panel lists concerning their duties and remuneration; and whether he had conferred with the approved societies in relation to such matters. Sir William Joynson-Hicks replied he had now made two alternative offers to the doctors, which would be considered by the conference on November 14th. As regards the second part of the question he stated that for some months past a series of consultations had been taking place with the Approved Societies' Consultative Councils of England and Scotland, and, in addition, conferences had been held with representatives of the various important groups of approved societies in Great Britain in relation to both duties and remuneration.

In reply to further questions, Sir W. Joynson-Hicks said that if his offer was accepted he hoped to lay on the table a White Paper on the whole subject, including an actuarial report. Asked whether the agreement had been assented to by the approved societies, Sir W. Joynson-Hicks said, "No, sir. I, as Minister of Health, after fully considering the whole matter, have made alternative proposals to the doctors. If either of these proposals is accepted legislation will be necessary, and I hope to have the responsibility of bringing in that legislation and submitting it to the House."

## COMMERCIAL INFLUENCES IN THERAPEUTICS.

A. J. CLARK, M.D., F.R.C.P.,

PROFESSOR OF PHARMACOLOGY, UNIVERSITY COLLEGE, LONDON.

On taking the chair as President of the Section of Pharmacology and Therapeutics of the Royal Society of Medicine on November 13th, Professor CLARK, after thanking the Section for the honour it had done him, gave an address on the influence of commercial interests on therapeutics, in the course of which he made the following observations:

Certain work, done during the past few years, in examining widely advertised proprietary medicines, impressed upon me the light-hearted manner in which some firms made sweeping therapeutic claims for their products; claims in support of which they had little or no direct evidence. In addition I found that even when evidence was laboriously collected which indicated that these claims were erroneous, it usually made no difference in the advertised claims. This naturally caused me to inquire what safeguards existed in England to ensure that the claims made in advertisements of drugs were at least not demonstrably false. I found as a matter of fact that no such safeguards exist. Reputable firms, out of regard for the good name of their firm, are, of course, careful what claims they make in advertisements, but this is the only safeguard that exists.

I may say at once that, in my opinion, this state of things is extremely prejudicial to the progress of therapeutics, and that it is highly desirable that the medical profession should devise some sort of organization for its own protection in this regard.

The exploitation of therapeutics by large commercial concerns really only developed in the latter half of the nineteenth century. It is true that a company was formed in Paris shortly before the Revolution for the large-scale production of the Thériac, the famous mediaeval cure-all, but this company perished in the Revolution. Modern methods of advertising have enabled the exploitation of the public on a far vaster scale than formerly; moreover, a company with extensive capital can employ more skilled assistance in conducting propaganda, and hence there is a general tendency for the cruder forms of exploitation to disappear and to be replaced by much more refined methods. The production of drugs on a large scale has, of course, brought many very important benefits to medicine, for it has rendered possible the production of drugs of uniform quality, and has been of great help in the organized search for new remedies. But although the capitalization of the drug industry has rendered important services to medicine it is idle to deny that it has also introduced serious new evils.

It was recently estimated that the capital employed in America in making secret remedies was larger than that employed in the legitimate drug trade. In England it was estimated that in 1913 more than £4,000,000 was spent on such remedies, and that the trade spent £2,000,000 in advertising. I quote these statements as evidence that there exists a very powerful and extensive trade which exploits the public; as I shall show later, there is no guarantee that this trade may not turn its attention to the medical profession if it conceives that such exploitation will yield quicker profits than exploitation of the general public. At present the medical profession has practically no organization available for its defence against such a move.

It is important to note that the law affords no protection whatever to the public or to the medical profession against any form of exploitation by proprietary medicine vendors as long as they avoid the laws against obscenity. The law on the subject was summarized in the report of the Select Committee on Patent Medicines in 1914<sup>1</sup> as follows:

Para. 22. "The situation, therefore, as regards the sale and advertisement of patent and proprietary medicines and articles may be summarized in one sentence as follows. For all practical purposes British law is powerless to prevent any person from procuring any drug, or making any mixture, whether potent or without any therapeutical activity whatever (so long as it does not contain a scheduled poison), advertising it in any decent terms as a cure for any disease or ailment, recommending it by bogus testimonials and the invented opinions and facsimile signatures of fictitious

physicians, and selling it under any name he chooses, on the payment of a small stamp duty, for any price he can persuade a credulous public to pay."

The Committee also came to these additional conclusions:

Para. 55. "(7) That the existing law is chaotic and has proved inoperative, and that successful prosecution for fraud in the advertisement and sale of secret remedies is fraught with the gravest difficulty, though the Public Prosecutor has perhaps not sufficiently tested the powers of the existing law in respect to such cases.

"(8) That consequently the traffic in secret remedies, except as regards scheduled poisons and the grosser forms of impropriety, is practically uncontrolled in this country."

The objection will at once be raised that these paragraphs refer to the blatant frauds advertised in the lay press, frauds which the medical profession has consistently denounced, and which really are of little concern to medical men. Unfortunately it is impossible to make any easy definition which will divide these blatant frauds from proprietary medicines of highest therapeutic value. These extremes are so utterly dissimilar that it is hard to believe that there is any relation between them, but every possible intermediate grade exists, and it is a matter of utmost difficulty to establish any formula to determine which proprietary articles should be recognized by the medical profession and which should be condemned. There is in fact no definite line that can be clearly drawn between quack medicines and legitimate proprietary articles.

There are, of course, certain classes of articles that the medical profession can condemn at once.

In the first instance secret remedies require no discussion, for it is contrary to every professional tradition for a doctor to prescribe a remedy of whose composition he is ignorant. The advertisement of a secret remedy is, however, merely an indication of a lack of ingenuity and imagination on the part of the manufacturer. Nothing is simpler than to give a formula and to claim either that one of the ingredients is obtainable only by the manufacturer, or that the value of the medicine depends upon the exquisite skill with which the ingredients are prepared and compounded.

As an example of a non-secret proprietary remedy one may take the preparation sold by Mr. C. H. Stevens. Stevens first sold remedies for pulmonary tuberculosis in South Africa named "Sacco" and "Lungsava." He then came to London and claimed that his preparation was not a secret remedy in that he was willing to give the formula to any doctor who requested it. The formula was stated to be 80 grains of Umkaloabo root and 13½ grains of Chijitse to every ounce, prepared according to the *British Pharmacopoeia* methods. Careful inquiries by the British Medical Association expert in South Africa failed to show the existence of Umkaloabo or Chijitse, nor could any record of them be found in any work on pharmacy. The Select Committee on Patent Medicines examined Stevens's cure (para. 43) and the Government Chemist gave the following analysis:

	Sample First Bottle.	Sample Last Bottle.
Proof spirit ... ..	19.5 per cent.	12.5 per cent.
Solid matter ... ..	2.8 "	3.4 "
Mineral substance (ash) ...	0.2 "	0.2 "
Glycerol (approximately) ...	10.7 "	17.8 "

"No alkaloids or resins were found. The solid matter corresponds with the colouring and extractive substances of an ordinary wine. The samples are therefore essentially mixtures of wine and glycerol."

Stevens brought an action against the British Medical Association for statements made regarding his remedy in *Secret Remedies*, and as the Select Committee notes, "the defendants pleaded justification, and the jury found for the defendants." In 1915 the "cure" appeared in the United States as the "U.P. Extract" exploited by the Umkaloabo Chemical Company of New York City.

During the past three years articles have appeared in the Swiss medical journals, in which Dr. Sechehaye<sup>2</sup> is reported to state that he has treated numerous cases of tuberculosis with Umkaloabo, and that it has acted as a real specific in tuberculosis. It would appear that these articles and conclusions are being broadcasted to the medical profession of this country.

I have spent so much time on this particular case because it is an example of a non-secret remedy supported by an article by a medical man published in a reputable journal. The Government Chemist's report is sufficient evidence that this is not the type of proprietary article that we would wish to see supported by the medical profession in this

on his work, never hurried, always untroubled and prompt in the face of a mishap. In the subsequent management of a case he was never out of the way in case of emergency unless (as when called away) he had made ample provision; in short, his patient was able to feel that she was never one of his mind until she was well. As regards his non-professional side, he was an unusually kind and sympathetic friend, in joy or in sorrow. In the holidays, when his delight was to stay, he always took care of his guests first, and put himself last. There was another side of him which was known only to very few, and to which he never referred to me—namely, his care for his poorer patients. It was his wont to follow their fortunes on their discharge from hospital, and to help pecuniarily those who needed help, his reason being that, as they had helped him indirectly to prosperity, it was only fair that they should not be forgotten.

Mr. F. R. Cross, surgeon to the Bristol Eye Hospital, and reader in ophthalmology in the University, writes:

My friendship with Harrison Cripps dated from the time that we were fellow residents in King's College Chambers. He was in the engineering department, and would no doubt have done well, as he had a mechanical turn of mind and showed ingenuity in the invention of instruments—one that was exhibited at the Royal Society on the "continuous registration of heat," and others.

Yet he was drawn towards surgery, became a student at St. Bartholomew's, rapidly qualified, and was demonstrator of anatomy. His natural ability and industry were aided by a quiet self-confidence that always characterized him.

Thus almost directly after he passed the examination for the Fellowship of the College of Surgeons he gained the Jacksonian prize for an essay on "Cancer of the rectum and its cure by excision." This was followed by a book that started his successful career in this branch of work: it was illustrated by many drawings by Mrs. Cripps and himself taken from microscopical sections he had made from his cases. But more than this, he was a good all-round surgeon and teacher. Perhaps not a man of many friends, he was very sociable, and hospitable to those he knew well.

He was a good shot and fisherman; and as a younger man he enjoyed what time he could give to a day's hunting, particularly with his father's private pack of harriers near Parmoor. Later on, when he took a lease of Abbotford, the house was, during the long vacation, filled with his friends for whom he found daily amusement on the grouse moors, or in salmon fishing in the Tweed. His hospitality was unbounded—his great care seemed to be to think for the individual interests of his many guests, leading the way in sport by day, and in the evening keeping us all together, by chess conversation at dinner or by the fireside. This hospitality was continued year by year, and afterwards when he purchased Glendarnel in Ayrshire.

In 1905 he was elected to the Council of the College of Surgeons as a substitute member for three years, but was not re-elected. With characteristic courage, however, he tried again in 1909, was successful, and remained a member until 1920. He was well fitted for the independence that characterizes the actions of the members of Council; while his long experience as a hospital surgeon, his sound common sense and knowledge of business, were of great service. I look back with pleasure to the times I spent with him and many of our friends, and with gratitude to Cripps and Mrs. Cripps for hospitality in London and Abbotford, and later when he became the Laird of Glendarnel; there it is that he is lying now in peace, surrounded by the valleys and mountains that he loved so well.

THOMAS HENRY GREEN, M.D., F.R.C.P., Consulting Physician to Charing Cross Hospital and to the Hospital for Consumption and Diseases of the Chest, Brompton.

The death of Dr. Thomas Henry Green on November 5th 1921, at Charing Cross Hospital, became M.R.C.S. in 1864, M.B. Lond. in 1865 with first-class honours in medicine, and proceeded to the University of Edinburgh, and graduated M.B., C.M. in 1861. He was educated at University of Edinburgh, and was a physician to the hospital. He was for no less than twenty-eight years of that period he was Charing Cross Hospital Medical School for thirty-five years; in his eighty-second year removes one who loyally served for Consumption and Diseases of the Chest, Brompton.

to the M.D. in 1866. After holding various posts at University College Hospital and that of medical registrar at the Hospital for Sick Children, Great Ormond Street, he was in 1868 elected assistant physician to Charing Cross Hospital; this migration from University College to Charing Cross Hospital was initiated in 1871 by Sir R. Douglas Powell and the late Dr. Vivian Moore, and in 1876 by Sir Thomas Barlow. From 1874 to 1902, when he retired and became consulting physician, he was full physician, and the excellence of his clinical teaching will long be held in grateful remembrance by many generations of old students of the hospital, who, it is said, found it unnecessary to read any textbook of medicine for examinations provided they attended Green's clinical teaching. As lecturer on pathology and morbid anatomy he set a high standard of teaching from the time he joined the hospital staff until 1887, and from 1870 to 1874 he was in addition curator of the museum. At the Hospital for Consumption and Diseases of the Chest, Brompton, he was elected on June 17th, 1875, together with his colleague at Charing Cross Hospital, Dr. J. Mitchell Bruce, assistant physician, becoming physician in December, 1898, and consulting physician in February, 1903. He became a member of the Royal College of Physicians of London in 1867 and a Fellow in 1874, and was Censor (1900-1), Senior Censor (1904), and for eight years an examiner. At the time of his death he was sixtieth in seniority on the list of Fellows.

Green was a representative hospital physician of the best contemporary type with a solid basis of morbid anatomy for his clinical practice. Of a retiring disposition he was seldom in evidence, and less so in the later part of his professional career, possibly as the result of a serious illness from which he made a complete recovery, than in his earlier days. At the old Pathological Society of London he was secretary (1875-6), vice-president (1885-8), and served twice on the Council (1877-8, 1878-9). He was also on the Council (1886) and a referee for papers (1892-1906) at the Royal Medical-Chirurgical Society, and when the Royal Society of Medicine started he was one of the first vice-presidents (1907-8) of the Section of Medicine. He also served on the Council and made four contributions to the Transactions of the Clinical Society of London. From comparatively early days he was widely and chiefly known as the author of an *Introduction to Pathology and Morbid Anatomy* which first appeared in 1871 (12mo, pp. xvi and 534; 60 figures) and was translated in 1876 and again in 1886 into Japanese. After Green gave up the pathological lecturing the hand-book was rightly regarded by students as a standard textbook, the teaching of Virchow, under whom Green had worked, G. S. Wilson (1893, 8vo, pp. 624; 244 figures). Embodiment and edition under the direction of Drs. W. C. Bosanquet and has now passed its jubilee in the much expanded thirtieth edition (12mo, pp. xvi and 534; 60 figures) and appeared in 1871 (12mo, pp. xvi and 534; 60 figures) and was translated in 1876 and again in 1886 into Japanese. After Green gave up the pathological lecturing the hand-book was rightly regarded by students as a standard textbook, the teaching of Virchow, under whom Green had worked, G. S. Wilson (1893, 8vo, pp. 624; 244 figures). Embodiment and edition under the direction of Drs. W. C. Bosanquet and has now passed its jubilee in the much expanded thirtieth edition (12mo, pp. xvi and 534; 60 figures) and appeared in 1871 (12mo, pp. xvi and 534; 60 figures) and was translated in 1876 and again in 1886 into Japanese.

It was followed by the late Dr. Monaghan Murray, and then by Dr. Bosanquet, who in 1917, in conjunction with Professor W. W. C. Topley, was responsible for the twelfth edition. In 1876 he published a small book of 103 pages on *The Pathology of Pulmonary Consumption*, which consisted of three lectures given in the previous year at the Brompton Hospital. This contained illustrations from his book on pathology and expressed views originally put forward four years previously in a series of papers in the *Medical Times and Gazette*. Quain's *Dictionary of Medicine* contained an article by him on inflammation of the lungs, and he made various, but by no means numerous, contributions to the medical journals.

This bare record shows the events in the life of a conscientious physician who was content to do the day's work without any further ambition than to have earned his own self-respect.

HENRY WHITBY PHILLIPS, M.D.,

Croydon.

He took the diploma of M.R.C.S. Eng. in the same year. He was a son of the late Charles Henry Phillips was a son of the late Charles Phillips of Atherstone, Warwickshire, and a brother-in-law of the late Dr. G. A. Gibson of Edinburgh. He studied at Edinburgh, and graduated M.B., C.M. in 1861.

## THE EXPERIMENTAL BASIS OF ENDOCRINE THERAPY.

BY

A. J. CLARK, M.C., M.D., F.R.C.P.,

PROFESSOR OF PHARMACOLOGY, UNIVERSITY COLLEGE, LONDON.

The laboratory worker and the clinician naturally regard the therapeutic measures from a slightly different angle, since the former is concerned chiefly to know what facts can be considered as fully proved, and the latter wishes to know what measures offer a fair chance of benefiting patients. The history of therapeutics teaches us, however, with no uncertainty, that once speculation and imagination get free from the restraint of rigidly controlled observation there is no limit to the distance which they may wander from the paths of truth. Complete systems of treatment based on inaccurate deductions have repeatedly been built up, and have been almost universally accepted and followed until some advance of knowledge, or even some change in fashion, has sufficed to upset the whole system, and the treatment has been universally discarded and often has come to be regarded as not only useless but actually harmful.

When considering any system of treatment it is very necessary to distinguish clearly between that part of it which is definitely proved and that part which is based merely on plausible deductions, and in no case is this attitude more essential than when considering the recent developments of endocrine therapy.

The discovery of the organs of internal secretion opened up a whole new field of physiology, and this knowledge led to brilliant and dramatic successes in the treatment of thyroid deficiency. This initial success suggested boundless possibilities in the use of organ extracts, and endocrine therapy has gone forward on the assumption that extracts of every other organ of internal secretion ought to yield results comparable to those obtained from thyroid therapy. There has been every temptation for therapeutic practice to outrun scientific fact, and in addition commercial enterprise has certainly done its full share in assisting in the development of endocrine therapy. The result is that endocrine therapy is coming to bear a suspicious resemblance to medieval magic; the savage believes that eating the heart of his enemy will confer on him the virtues of this enemy, and the more enthusiastic vendors of endocrine remedies suggest that the consumption of extracts of practically any organ will cure diseases of that organ. The general line of thought and the extent of scientific foundation are about the same in both cases.

These considerations indicate how essential it is in the case of endocrine therapy to examine the evidence closely and distinguish clearly between the remedies whose use is based upon definite evidence, and those whose use is simply based on inference. The subject of endocrine therapy can be divided into two fairly distinct divisions: (1) substitution therapy—that is, the administration of the extract of an organ in order to compensate for the deficient secretion of the organ; and (2) the use of extracts of tissues as pharmacological agents, when there is no question of substitution for a deficient secretion.

The use of adrenalectomy as a vaso-constrictor and the use of pituitary extract as an oxytocic are examples of the second class of action. In those two particular cases extracts of endocrine organs are used, but active pharmacological agents can also be obtained from other kinds of tissues. For example, Abel and Macht found that the poison gland of the Medical Association.

Substitution therapy is the most important division of endocrine therapy, and it is advisable to consider the postulates that should be fulfilled before we can assume that an organ extract acts in this way. Glye<sup>1</sup> has laid down three conditions which should be fulfilled before it is assumed that an organ produces an internal secretion.

1. The histological condition. The organ must contain secretory cells in intimate relation with the blood vessels and without any duct for external secretion.

2. The chemical condition. A specific chemical substance must be identified both in the organ and also in either the venous blood or lymph coming from the organ.

3. The physiological condition. The venous blood or lymph coming from the organ must produce the pharmacological actions produced by the specific substance.

Glye<sup>1</sup> has recognized that these conditions are so severe that they would rule out most of the endocrine organs, and has suggested that in default of the above conditions two other concurrent tests may be accepted—namely, (1) the destruction of the gland produces deficiency symptoms which present a clearly defined syndrome; and (2) this syndrome is relieved by grafting of the gland or by administration of organ extracts.

These tests of Glye's are framed to test the physiological actions of organs, but from the point of view of pharmacology slightly different tests are required. For example, even if grafting of a gland produces benefit in a deficiency syndrome, it does not follow that the administration of organ extracts will be successful.

Endocrine therapy may be considered to rest on a solid scientific foundation when the following conditions are fulfilled: (1) The destruction of a gland produces a characteristic syndrome. (2) The administration of extracts of the organ relieves this syndrome. (3) Some chemical or pharmacological test exists by which the activity of the extract can be recognized and if possible be measured. It is important to realize that even if the first condition is fulfilled it does not follow that the second condition will also be fulfilled.

An endocrine organ may fail to produce an active extract for several reasons. (1) The action of the gland may be in part or entirely a detoxicating action, in which case the administration of gland extracts will have no effect. (2) The gland may secrete its internal secretion as rapidly as it is formed. In such a case the gland will contain no store of internal secretion and its extracts will be inert. (3) The active principle may be so labile that it cannot be isolated. In any of the above three cases grafting of the gland may be expected to relieve deficiency symptoms, but administration of gland extracts will produce no effect. All the known hormones are relatively unstable bodies, although some are much more unstable than others, and it is interesting to consider that Minchowski, as early as 1889, showed that removal of the pancreas produced diabetes, but it was more than thirty years before anyone succeeded in isolating the active principle of the pancreas in a stable form. Another difficulty is that it is necessary to discover the correct method of administering organ extracts, for in many, if not most, cases these are destroyed in the gut before absorption. These considerations show how wide is the step between proving the effects produced by deprivation of an internal secretion and the discovery of the correct method of providing the effects produced by deprivation of an internal secretion. Unless some test exists by which the activity of an organ extract can be recognized these difficulties are almost insuperable.

So-called endocrine remedies have been prepared from every tissue of the body, but it is only necessary to consider those organs which fulfil the first condition—namely, that

Shortly after graduation he became house-physician to the late Dr. George Balfour in the Royal Infirmary, Edinburgh. After holding various other hospital appointments he graduated M.D. with honours in 1886. He then settled in Croydon, where he rapidly established himself in an extensive practice, and remained for thirty-four years. During the war he served as an officer of the Volunteer Force, in the Surrey Royal Army Medical Corps, and was granted the honorary rank of major, receiving on retirement the thanks of the Army Council. He was also on the staff of the Croydon War Hospital, and was latterly entrusted with the organization of a volunteer ambulance corps. Not content with this he made several attempts to serve overseas, and the fact that he was prevented from going abroad by the age regulations and on account of medical reasons was a great disappointment to him.

In the midst of a busy life he found time for many interests. He was a member of the Alpine Club and a skilful and intrepid climber, and year after year he spent his holidays among the mountains, and had ascended many of the more inaccessible peaks in the Swiss and French Alps. Though the loss of an eye, supposed by some to have been due to several attacks of snow blindness, prevented him from continuing to indulge in his favourite hobby, he still kept up his interest. He was an enthusiastic member of the Pepys Club, and was actively interested in several literary and art societies. Believing to the fullest extent that a medical man should be well instructed and well read, amid the wide circle of his interests he kept himself fully abreast of the recent advances in medicine and surgery. In the company of a sympathetic listener he was at his best in his Alpine garden on a summer evening, pointing out his most choice and favourite specimens and telling tales of his beloved mountains; or, wandering through the dim twilight of one of our ancient cathedrals, delighting his audience with his profound knowledge of religious architecture. Those who met him quickly recognized him as a man of great enthusiasms and wonderful versatility, of broad views and independent thought, a lover of all things beautiful, whether the work of nature or of man. Those who were privileged to know him intimately remember him as kindly and gentle, more especially to those most needing his assistance, preserving through his life the same high ideals with which he first set out on his journey, and supporting through the later years of his life an ever-increasing ill health with indomitable fortitude and without complaint.

**THE LATE DR. WILLIAM HALL OF LEEDS.**—In response to our request Sir James Crichton-Browne has sent the following brief note: "I have seen nothing of the late Dr. William Hall of Leeds for forty years. While resident in the West Riding I met him many times in consultation, and found him a wise, broad-minded, and thoughtful physician, sympathetic and judicious and of refined and genial presence. He took an active part in the campaign against overpressure in elementary schools and the pernicious system of payment by results, and shamed us by his demonstration of the superior hygienic conditions under which Jewish children are reared. He was a delightful friend, a worthy member of the shining professional hierarchy in Leeds in those days."

**DR. HENRY LIONEL SMITH**, of Mottingham, Eltham, who died in a nursing home at Blackheath on November 3rd, aged 80, had had a much more varied experience than falls to the lot of most men of his profession. He was the eldest son of the late Henry Joseph Smith, F.R.C.S.I., of Donaghmore House, Queen's County, Ireland, was educated at the Ledwich School, Dublin, and took the L.R.C.S.I. and L.K.Q.C.P. in 1866, and the M.R.C.P.I. in 1885. He began his career in the service of the Hudson's Bay Company, when he was stationed at Moose Fort, at the southern end of Hudson's Bay; he then went to Australia, where he was for some time district surgeon at Albany, West Australia; and finally served in South Africa, where he was surgeon to the Mashonaland Police; saw active service in the Mashona rising, and received the medal for that campaign; afterwards he held the posts of district surgeon and M.O.H. at Bulawayo, the capital of South Rhodesia.

THE well known bacteriologist and hygienist, Dr. KARL FLÜGGE of Berlin, has recently died, at the age of 75.

Professor FRIEDRICH MARTIUS, formerly director of the Rostock University Medical Clinic, and a well known writer on achylia gastrica and the relation of heredity and constitution to pathology, died recently, at the age of 75.

## The Services.

### DEATHS IN THE SERVICES.

Colonel Sinclair Westcott, C.B., C.M.G., D.S.O., Queen Alexandra's Military Hospital, died on October 14th, aged 64. He was born at Plymouth, England, in 1859, educated at St. Bartholomew's Hospital, and took the M.R.C.S. in 1880, and the L.R.C.P. Edin. in 1881; he took the D.P.H. Dublin in 1899. He entered the R.A.M.C. as surgeon in 1882, he attained the rank of colonel in 1912, and retired on December 26th, 1917. He was medical officer of health at Hong Kong during the plague epidemic of 1895 in that colony, the first outbreak of the great visitation of plague which has ever since been more or less endemic in the Eastern hemisphere, and has ravaged India almost continuously since it was first detected in Bombay in 1896. He served in the South African war from 1899 to 1902, and took part in the defence of Ladysmith. Afterwards he was in charge of a general hospital, with the temporary rank of colonel, served in the operations in the Orange River Colony, was twice mentioned in dispatches, in Sir George White's dispatch of March 23rd, 1903, and Sir Redvers Buller's of November 9th, 1900, both published in the *London Gazette* of February 8th, 1901, and again in the *London Gazette* of September 10th, 1901. He received the Queen's medal with three clasps, and the King's medal with two clasps, and the C.M.G. In the war of 1914-18 he served first as A.D.M.S. of the First Division, and afterwards as D.D.M.S. of the First Army Corps, was six times mentioned in dispatches, in the *London Gazette* of December 4th, 1914, June 22nd, 1915, June 15th, 1916, and May 29th, 1917, and received the C.B. in 1915. He was also a Knight of Grace of the Order of St. John of Jerusalem. From 1918 to 1920 he served under the Ministry of Pensions as a deputy commissioner of medical services. In 1898 he married Ethel Constance, daughter of Colonel the Hon. Robert Bradshaw, and widow of D. Gifford Otley, and leaves one daughter.

Colonel Geoffrey Craythorne Hall, Bengal Medical Service (ret.), died at Bexhill on October 27th. He was born at Grahamstown, South Africa, on August 27th, 1848, and educated at Guy's Hospital; he took the M.R.C.S. and the L.R.C.P. Edin. in 1871, and the F.R.C.S. in 1894. He entered the I.M.S. as assistant surgeon on March 30th, 1872, and attained the rank of colonel on December 2nd, 1901, but retired less than a year after. Before entering the service he had taken part in the Franco-German war of 1870-71, serving in a field ambulance, and received the German war medal. In India, after a few years' military duty, he entered civil employ in the North-West, now the United Provinces, and spent almost the whole of his services in the jail department of these provinces. For the greater part of the time he was superintendent of the large central jail at Naini, near Allahabad, but rose to be Inspector-General of Jails in the province. While at Naini he founded an ophthalmic hospital at Allahabad, kept up by private subscriptions, and for many years had a great reputation as an ophthalmic surgeon. He was the author of a number of small books on eye surgery—books which, without being very scientific, were of great help to the young civil surgeon beginning to do eye surgery in a district hospital remote from the help or advice of more experienced officers: *Causes of Blindness in India*, 1879; *Eye Diseases of Children*, 1884; *Complications of Cataract Operations*, 1886; *Senile Cataract*, 1899; *When to Wear Glasses*, 1900.

## Medical News.

THE new session of post-graduate courses and demonstrations for 1923-24, arranged by the Faculty of Medicine of the University of Sheffield, commenced on Friday, November 16th, and will be continued on Tuesdays and Fridays at 16th, with the exception of a break from December 18th, 1923, till January 25th, 1924. The lectures will be announced in the weekly diary published in the SUPPLEMENT.

WE may remind readers that the lecture by Professor Strandberg of Copenhagen, on the results of treatment of rhino-laryngological tuberculosis by the Finzen light bath, will be delivered before the Royal Society of Medicine on Monday, December 3rd, at 5.30 p.m.

A REPORT by the medical committee of the Canadian Social Hygiene Council on the standardization of the diagnosis and treatment of venereal diseases has been issued by the Department of Public Health at Ottawa. The committee consisted of thirty-five medical men and women under the chairmanship of Dr. Edmund E. King of Toronto, and the editorial supervision of Dr. J. J. Heagerty, chief of the Division of Venereal Disease Control in the Dominion

my series there were in all 509 patients up to the end of 1923—243 males, 66 females, or 1:3.7. Table I gives information concerning the type of patient, the height of systolic blood pressure, and the incidence of valvular disease. There were 35, or 11.3 per cent., in whom I had a diagnosis of valvular disease of the heart. There was definite aortic regurgitation in 26, and some degree of obstruction in 10 patients.

Among many points of interest there are two which particularly attract our attention: (1) the relation of the ro-cardiographic findings to prognosis, and (2) the most and prognosis of minor angina.

# DEFINITION OF ANGINA.

Before considering these two points a general but cursory survey of the problem may be permitted, and it would be of state at once what the term "angina" signifies.

Angina pectoris I have in mind an arresting form of pain, subsernal rather than submammary, in which the patient is conscious of a sense of oppression, or constriction, which may reach a high grade of intensity, even to intolerable anguish. This pain has certain recognized lines of radiation and is often induced by exertion or emotion. There are in addition characteristic associated symptoms not invariably present—notably the sense of impending death, and indescribable anguish of mind accompanied by varying vasomotor disorders, such as cold and deathly pallor. It is well to remember that the information desired by patients and his friends refers more often to the duration of the attack than to the mode of death, although the latter is not infrequently the subject of their inquiries.

# Mode of Death.

The first important factor when considering the mortality of angina is clearly that an anginous patient does not necessarily die in an anginal seizure, but frequently from some degree of justifiable confidence. The outlook depends on the integrity of the myocardium, and the health of the general arterial tree. It will depend also on the degree of co-operation given by the patient, who must be honest with himself and prepared to live down to the level of his damaged organs. Death is often the outcome of the associated conditions and the cry of the heart is nothing more than the signal that it also is involved in the general depreciation. What ever indicates a tendency to cardiac failure is of significance, and search must be made for every evidence of myocardial disease or functional impairment. [The lecturer then dealt with the effect of transient toxæmia on the myocardium and referred to dyspnoea and the pulsus alternans as evidence of myocardial inadequacy. The grave significance of the alternating pulse was emphasized.]

In patients suffering from angina the significance of hypertension apart from the possibility of associated kidney disease lies in the fact that a raised blood pressure adds to the

If we accept the view that sudden death in these patients is usually due to fibrillation of the ventricle, and the clinical and experimental evidence favours this supposition, it is of interest to consider the factors predisposing to this lethal tumult of the myocardium. This has a definite bearing on prognosis. Professor J. A. McWilliam pointed out in August last that the exciting cause of fibrillation is "an increased demand on the powers of the heart and more or less stress on the organ"—for example, muscular effort or emotional excitement. Fortunately such factors leave the normal heart unaffected and are capable of inducing fibrillation only when the heart is in an abnormal condition of excessive susceptibility. Certain drugs such as digitalis increase the liability to fibrillation, and there are probably other drugs and abnormal conditions with a similar tendency, but a "prominent part in the setting up of abnormal susceptibility to fibrillation must be assigned to defective coronary blood supply." The condition of the coronary arteries is therefore one of the important factors to be considered when estimating the liability to sudden death.

The liability to death during an anginal seizure in any particular case is almost incalculable, and I frankly admit that I know of no certain rule by which one can decide as to the probability of a sudden, dramatic, and painful attack. An increase in the frequency and severity of the attacks is obviously ominous, but even when this has appeared unexpectedly is not removed. The first attack may come like a bolt from the blue. The first attack may be the last, with possibly no premonitory sign or signs to indicate that death is on the threshold. It is also well recognized that the severity and gravity of the initial seizure give no indication of the liability to an early recurrence, though in the presence of the attack itself, confronted by the physical and mental distress, it is difficult and almost impossible to take this dispassionate view. If, however, the patient survives the first stormy onset years may pass before there is any recurrence of a comparable severity. While recognizing the elusive and incalculable element of uncertainty and frankly admitting the possibility of a sudden and terminal anginal seizure, I believe that the expectation of life in these patients can be predicted with some degree of justifiable confidence. The outlook depends on the integrity of the myocardium, and the health of the general arterial tree. It will depend also on the degree of co-operation given by the patient, who must be honest with himself and prepared to live down to the level of his damaged organs. Death is often the outcome of the associated conditions and the cry of the heart is nothing more than the signal that it also is involved in the general depreciation. What ever indicates a tendency to cardiac failure is of significance, and search must be made for every evidence of myocardial disease or functional impairment. [The lecturer then dealt with the effect of transient toxæmia on the myocardium and referred to dyspnoea and the pulsus alternans as evidence of myocardial inadequacy. The grave significance of the alternating pulse was emphasized.]

In patients suffering from angina the significance of hypertension apart from the possibility of associated kidney disease lies in the fact that a raised blood pressure adds to the

Department of Health. The report recommends that all laboratories, including university laboratories, doing Wassermann tests, shall be licensed by and under the supervision of the Provincial Board of Health, and urges private, university, hospital, municipal, and provincial laboratories, in the use of these tests, to adopt recognized methods, so as to approach uniform results for the purposes of comparative study.

The memorial to the late Professor Sir German Sims Woodhead at the Cambridgeshire Tuberculosis Colony, Papworth Hall, consists of a new pathological laboratory and x-ray department. It will be opened on Thursday next, November 22nd, at 2.30 p.m., by the Hon. Sir Arthur Stanley, G.B.E. The hospital, hostels, workshops, and village settlement will be open to visitors from 2 to 4.30 p.m.

DR. GEORGE CHAPMAN, of Hall Green, Birmingham, has celebrated this month his 100th birthday. He was a member of the British Medical Association for forty-five years. The Lord Mayor of Birmingham has sent him a congratulatory letter.

THE Schörstein Memorial Lecture will be delivered by Dr. Gordon Holmes, C.M.G., in the Anatomical Theatre of the London Hospital Medical College, on Monday, December 3rd, at 4.15 p.m.; the subject selected is some symptoms of cerebral irritation.

THE Duke of Bedford (President) and the General Committee of University College Hospital are giving a dinner at the Savoy Hotel, London, on Tuesday next, November 20th, when H.R.H. Prince Henry will be in the chair. Further information can be obtained from Dr. Walter W. Seton, University College, Gower Street, W.C.

THE annual dinner of the London School of Tropical Medicine will be held at the Hotel Victoria on Wednesday, November 21st, under the presidency of Sir Ion Hamilton Benn, deputy chairman of the Seamen's Hospital Society and the School.

THE annual dinner of the Medico-Legal Society will be held at the Holborn Restaurant on Friday, December 14th, at 7 for 7.15 p.m., when the president, the Right Hon. Lord Justice Atkin, will be in the chair.

THE bi-annual dinner of the Aberdeen University Club, London, will be held on Tuesday, November 27th, at Gatti's Restaurant, with Lord Elphinstone in the chair. The principal guest will be the Right Rev. Professor G. Milligan, D.D., D.C.L. The hon. secretary, Dr. Anstruther Milligan, 11, Upper Brook Street, W.1, will be very pleased to hear from any past or present graduates, men or women, wishing to attend the dinner.

ADMIRAL OF THE FLEET EARL BEATTY will preside at a festival dinner in aid of the Royal Northern Group of Hospitals to be held at the Mansion House on Wednesday, November 21st, at 7.30 p.m. The particular object of the dinner is to help to reopen seventy beds now closed.

AN exhibition of scientific novelties will be held at King's College during the Christmas holidays, from December 29th to January 9th inclusive, between the hours of 2 and 9 p.m. Experiments and demonstrations will be given continuously during this period and illustrated lectures will be delivered by Professor Cheshire, Professor Winifred Cullin, Sir Richard Gregory, and others. The proceeds will be given to the King Edward's Hospital Fund for London.

THE annual meeting of the Medical Officers of Schools' Association will be held at 11, Chandos Street, W.1, on Thursday, November 29th, at 5.15 p.m., when Dr. H. Crichton Miller and Dr. H. C. Cameron will open a discussion on the nervous child.

IN his recent presidential address to the Bolton and District Medical Society Dr. John Johnstone surveyed the medical history of the town, dealing particularly with the characters of the medical practitioners who had lived in it. It was remarkable, he said, how many Bolton medical men had belonged to the same families, twelve families having provided thirty-four medical practitioners among them. In 1814 there were known to have been two medical men in Bolton, while at present there were eighty-five practitioners, including seven ladies.

SIR JAGADIS BOSE, F.R.S., director of the Bose Institute, Calcutta, will deliver a lecture at the Royal Society of Medicine on Thursday, December 6th, on assimilation and circulation in plants. The chair will be taken by the president of the Society, Sir William Hale-White, at 5.30 p.m., and the apparatus used will be demonstrated in operation.

DR. LOUIS C. PARKES will take the chair at a meeting at the Royal Sanitary Institute (90, Buckingham Palace Road, London) on Monday, November 26th, at 5 p.m., when Miss Muriel A. Payne, honorary secretary of the International School of Nursing and Child Welfare for Russia, will give an address on sanitary relief work in that country.

DR. LOCKHART STEPHENS, on his retirement from the post of medical officer of health for Emsworth, was entertained at a complimentary luncheon on November 6th, when he received a presentation from the members and officers of the Warblington Urban Council.

THE League of Remembrance was established to perpetuate the memory of the war hospital supply depot movement, which was so successful during the war. It maintains a supply of medical and surgical requisites and clothing for hospitals and other institutions engaged in the promotion of health or social welfare; it also provides financial assistance to the widows, children, and other dependants of officers who fell or were incapacitated in the war. The organization is maintained as a nucleus to be made available for mobilization or expansion in cases of national emergency, and it provides instruction by lectures in connexion with matter relating to the objects of the League. The headquarters of the League are at 1, Marlborough Gate, London, W.2, and include a dining room, club rooms, and work rooms. There are various classes of members, and subscriptions range from 2s. 6d. to 2 guineas.

A POST-GRADUATE course in oto-laryngology will be given in Vienna during the fortnight beginning Monday, December 3rd. Full particulars can be obtained from Dr. Kronfeld, Porzellangasse 22, Vienna IX.

THE seventy-fifth anniversary of the foundation of the Amsterdam Medical Society in 1848 was celebrated by a banquet and by an interesting historical loan exhibition. The Amsterdam Medical Society is now the Amsterdam Section of the Netherlands Medical Association.

AN institute for physical therapy and orthopaedics will be opened in Moscow in December.

IN New York, as in London, scarlet fever has shown a marked decrease this year. From January 1st to September 19th 6,832 cases have been notified, as compared with 8,622 cases during the corresponding period of 1922.

A CANCER INSTITUTE has been established in New York by the Commissioner of Public Welfare as part of the work of his department, and a series of clinical conferences of medical practitioners are to be held at which unusual cancer cases will be presented. The Institute is equipped for 200 patients.

UNDER the will of the late Elizabeth Skillern of Leyton, the London Hospital will, after payment of legacies, receive the residue of her property, which it is expected will amount to nearly £4,000.

THE Dutch Pediatric Society will hold its winter meeting at Amsterdam on November 25th, when the subject of empyema will be discussed.

JUPILLE, the second patient to be inoculated by Pasteur against rabies, has recently died. He held a post at the Pasteur Institute of Paris from its foundation until his retirement in 1918.

THE American Committee of Jewish medical practitioners has made a donation of £1,000 to purchase a piece of ground at Jerusalem for the erection of the medical faculty of the Jewish University.

A CONGRESS of tropical medicine was recently held at Saint Paul de Loanda in Portuguese West Africa on the initiative of the Portuguese Government; the subjects discussed were the organization of medical attention to the natives and the treatment of ankylostomiasis, malaria, sleeping sickness, etc. The next congress will be held in January, 1927, at Dakar.

A REGULATION has been passed by which every man and woman in greater New York who comes in personal contact with the public handling of food must obtain a licence from the department of health certifying that he or she is free from contagious and infectious disease; it is estimated that about 180,000 persons will require licences.

DR. C. V. PIQUET has resigned the post of head of the department of pediatrics of the University of Minnesota, U.S.A., after holding it for two weeks, and has returned to Vienna. Dr. v. Piquet stated that he had a feeling of homesickness for his Vienna hospital and was unable to adapt himself to the new conditions; moreover, the plans for a hospital, which were necessary for his researches, required a considerable time for completion.

IN Germany only 9 cases of small-pox and 22 of typhus occurred in the first six months of 1923, as compared with 199 and 358 respectively in the corresponding period of 1922.

THE sixteenth congress of the Russian Surgical Society will be held at Moscow from May 3rd to 8th, 1924. The subject for discussion will be pulmonary surgery, including abscess, gangrene, tuberculosis, and treatment of wounds of the lung. From January 3rd to 10th there will be a congress at Petrograd for pathology, experimental pedagogy, and psychoneurology.

to the load which the heart carries, and in addition is

generally associated with a diffuse arterio-sclerosis, so that this type of patient is predisposed to cardiac distress and cerebral accidents. Even so, the careful figures of Mackenzie<sup>1</sup> indicate that the expectation of life in anginal patients is not materially modified by an associated high blood pressure. This is an unexpected finding. In his series the mortality curve of those patients with a systolic blood pressure of 180 mm. Hg and over followed very closely that of the mortality curve of the whole series, though, if anything, death occurred a little earlier in his high blood pressure cases. The impression I have formed is that if it be found possible to modify even slightly an excessive blood pressure the symptoms of the patient are ameliorated, but I do not find that the expectation of life has been appreciably increased.

I have records of the age at death and duration of anginal symptoms in 60 patients. In 26 the systolic blood pressure was 180 mm. Hg or over—in them the average age at death was 60.8 years, and with only two exceptions

ages of 50 and 70. In the other 34 patients the systolic blood pressure was below 180 mm. Hg, and the average age at death (59.5 years) varied only slightly from the high pressure group. In each patient I have carefully inquired for the earliest manifestation of anginal pain, and I was surprised to find that the average duration of life from the first appearance of anginal pain was in fact shorter in the low pressure group. It was three years in the high pressure group; Fig. 1 shows graphically the age at death in the two groups.

Within recent years the functioning power and integrity of the myocardium have been investigated by means of the string galvanometer, and attempts have been made to correlate changes in the shape of the electro-cardiogram with prognosis. The fullest reports dealing with this have been from the Mayo Clinic at Rochester by E. A. Williams,<sup>2</sup> and B. S. Oppenheimer, N. A. Rosenthal, J. E. Mac-

Intensive figures bearing on this subject. Hitherto clinically the electro-cardiograph has been chiefly of value in analysing the various forms of arrhythmia. There are reasons for believing that in it we may find valuable assistance in prognosis. An electro-cardiogram represents graphically the variations in electric potential associated with each contraction of the heart. A normal systole is a co-ordinated contraction of the myocardium in response to a stimulus reaching it along well recognized channels. Under normal conditions the stimulus in an ordered sequence. It flows along the conducting channels and reaches the various areas of the myocardium at such time and in such a manner that the resultant systole of the whole heart is an efficient co-ordinated movement. Any break in the functional continuity of the conducting channels causes a deviation from this orderly sequence. These deviations are revealed in the electro-cardiogram. An abnormal electro-cardiogram therefore indicates that the fibres or groups of fibres composing the heart muscle did not contract in their proper relation one to the other. The commonest causes for this is some organic change in the myocardium, damaging or destroying the junctional tissues, due to some temporary cause may be solely responsible. An outstanding example of this change in the electro-cardiogram curve is met with when disease obliterates one branch of the A-V bundle. There is then a complete alteration in the ventricular complex. There are also

FIG. 1.—The 26 squares in black represent patients with a systolic blood pressure of 180 mm. Hg or over. The 34 squares in white represent patients with a systolic blood pressure below 180 mm. Hg.

Under each of these headings patients were arranged in clinical groups, and a careful series of controls collected comparable in age, sex, clinical type, and degree of decompensation. The total number of patients observed was 656 over a period of five and a half years. I have abstracted his figures dealing with angina; they are as follows:

TABLE III.

Control									
Total.									
Mortality.									
Per cent.									
Inverted T.									
A. Leads I, II, III, aVR, aVL, aVF.									
B. Q.R.S. 0.10 sec.									
C. All leads.									
D. A + B + C.									
Grand total.									
1	2	3	4	5	6	7	8	9	10
11	12	13	14	15	16	17	18	19	20
21	22	23	24	25	26	27	28	29	30
31	32	33	34	35	36	37	38	39	40
41	42	43	44	45	46	47	48	49	50
51	52	53	54	55	56	57	58	59	60
61	62	63	64	65	66	67	68	69	70
71	72	73	74	75	76	77	78	79	80
81	82	83	84	85	86	87	88	89	90
91	92	93	94	95	96	97	98	99	100

We see therefore that Williams dealt with 81 cases of angina manifesting certain definite abnormalities, and with 81 controls, patients comparable in every way except that their electro-cardiograms were normal. He obtained full information concerning 65 patients, and of these 45 died—giving a mortality of 66 per cent. In the 81 controls full information was obtained in 60, of whom 16 were dead—a mortality of 27 per cent.; that is to say, a mortality of 66 per cent. against a mortality of 27 per cent. Williams has no hesitation in stating that the higher mortality is the result of vascular degeneration of the obliterative type, and he considers that the abnormalities in the electro-cardiogram are directly caused by these degenerative processes. We cannot take this view as proved, though I believe we may fairly say that, other things being equal, an abnormal electro-cardiogram indicates the probability of degenerative changes in the myocardium, and in consequence a diminished expectation of life.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Mediscera Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Macillus, Dublin*); telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

## QUERIES AND ANSWERS.

### INCOME TAX.

#### Wear and Tear of Car.

"D. W." has been advised by his accountant that he cannot claim any allowance for annual depreciation of his car by wear and tear, but is entitled only to deduct as a professional expense the cost of renewal as and when incurred.

\* \* The advice is correct. The distinction in this matter between a "trade" and a "profession" is inequitable, but is the legal result of the existing statutes. The Royal Commission on Income Tax recommended that the distinction should be abolished, but it still exists.

#### Renewal of a Car.

"G. C. H." is in disagreement with the inspector of taxes about the renewal of a car; the inspector refuses to take into account the fact that the cost of cars rose during the period covered by the use of the original car, with the result that when a better car was bought the whole of the cost was not attributable to the improvement which was effected by the transaction.

"J. W. H." also asks a similar question.

\* \* An official witness before the Royal Commission on the Income Tax gave two examples of an allowance for renewal of a machine—vide Volume I, page 63, of the Evidence. The first made it clear that a rise in cost would not carry any restriction of the allowance if a similar machine were purchased, and the second shows that where an improved and more costly machine is purchased the transaction is to be regarded as twofold—that is, renewal *pro tanto*, plus improvement. In "G. C. H.'s" case the facts form a combination of the two examples quoted and seem, therefore, to require the treatment that he claims.

## LETTERS, NOTES, ETC.

### THE ADMINISTRATION OF CHLOROFORM.

DR. J. T. MACLACHLAN (Glasgow) writes: If chloroform is to be administered safely and fearlessly, certain fundamental principles must be observed, as follows: (1) No two people are alike as regards their tolerance for chloroform; each has his or her safe dose. (2) In order to find out the safe dose, chloroform must be administered slowly, and the dose gradually increased until the patient is under. (3) When the patient is under, chloroform should be suspended, perhaps only for a few seconds; the art at this stage consists in giving from time to time just sufficient to maintain anaesthesia. If these fundamental principles are obeyed, no death should occur from chloroform. A Skinner's mask is preferable to a towel, which hides the face; some masks are too large. The mask selected should be divided by imaginary lines into four quadrants, and one of the lower quadrants should be selected on which to drop the chloroform. I believe if this simple rule is adopted it is not at all likely that an overdose will

be given. If the patient coughs, it is a sure sign the chloroform is being rushed; the mask should be then lifted off the face for one inch or so for a few seconds. In the early stage of the administration it will be noticed that the patient's lips get rosy, and as long as they are so the anaesthetist may go ahead. Should they get blanched, chloroform must be instantly stopped, and ether dropped on the mask instead. A drop bottle containing ether must therefore be carried. The two accidents that may arise in the administration of chloroform, and which will not arise if the above rules are attended to, are apnoea and syncope. Apnoea gives timely notice; the patient gets blue, the head, and slap the chest vigorously with a towel dipped in cold water, not forgetting artificial respiration. If syncope sets in there is no time for syringes or electricity. The proper thing to do is to invert the body suddenly by raising the table two or three feet, and getting the blood to rush to the head. The chest, especially over the heart, should be slapped violently with a wet towel. But these conditions should never arise.

### ETHYL CHLORIDE-CHLOROFORM SEQUENCE.

DR. G. A. H. BARTON (London) writes: May I be allowed to reply to the queries of Dr. A. W. Burton (November 10th, p. 966) regarding the use of ethyl chloride as an induction agent? About 1904 I devised what I called the C.E.-ethyl chloride-chloroform induction sequence, and read and published papers on the subject, and later published a small monograph (*A Guide to the Administration of Ethyl Chloride*, H. K. Lewis and Co.) in which the method was fully described. Substituting ether for chloroform, I came to use the same sequence for open ether administrations. An account of this C.E.-ethyl chloride-E. H. K. Lewis and Co.) In 1912 Hornbrook (*Backwaters of Lethe, Anaesthesia*: Arbuckle, Waddell, and Fawcner, Melbourne) of Melbourne published some work he had done on somewhat similar lines, but the principles differ. In my method (semi-open) a narcosis is obtained, and it is during the anaesthesia that this becomes merged into the permanent chloroform or ether narcosis. In Hornbrook's (purely open) method the aim is rather to banish the patient and stimulate his respiratory centre, thereby hastening the intake of chloroform. So far as I know only two textbooks allude to this induction sequence, and in both it is, or was, attributed to Hornbrook. Closed ethyl chloride followed by chloroform I tried originally and gave up as dangerous, and the same method was, I believe, practised and abandoned by Silk. It is probably this method that Gwathmey and condemn. The semi-open method I use or the quite open one of Hornbrook is safe, certainly safer than a simple chloroform induction. I base this statement on an experience, including ether as well as chloroform cases, of nearly ten thousand inductions by my method.

DR. HAROLD SNAPE writes: I was anaesthetist before the war to the Manchester Children's Hospital, and for years, as a regular procedure, used an ethyl chloride-chloroform sequence or ethyl chloride-chloroform ether mixture sequence. I used a special inhaler consisting of a rubber bag connected with a plated tube bent at a right angle, its other end attached to a closed mask or facepiece; opposite to the straight piece of tube, leaving the bag, was a small shutter, which I opened to squirt the ethyl chloride into the bag and then shut. The inhaler was then ready for use and was applied till the child was under: it was then taken off and chloroform or chloroform-ether mixture administered on an open mask. By this means there was great saving of time and absence of struggling and excitement. I should not have continued with this method had it not been perfectly satisfactory. I would advise the chloroform or chloroform-ether mixture to be given very slowly to begin with as the breathing is so rapid and full with the ethyl chloride that unless this is fully realized an overdose is easily administered. I had one death with ethyl chloride alone in a case of tonsils and adenoids which I have not previously reported and which may be of interest. The patient was a boy, 12 years old, and after the operation was over came round, shouted, and sat up on the operating table and then collapsed and died. I diagnosed "status lymphaticus" as the cause of death, and the post-mortem examination proved this to be correct.

DR. H. J. VAN PRAAGH (London) writes: It may interest Dr. Burton to know that I started inducing with ethyl chloride early in 1917, when anaesthetist to the Cambridge Hospital, Aldershot, and 10 c.cm. ethyl chloride on to an open mask of six layers of gauze, and to follow it up with C.E., and finally open ether. In my opinion a closed inhaler should never be used. My colleague, Dr. Scott, I believe I am right in saying, used the same method. I have never had any trouble or anxiety with this procedure and find it a great saving of time, and a very pleasant method of induction from the patient's point of view.

### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 36, 37, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 38 and 39. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 235.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

**337. Erythredema Polyneuritis.**  
**D. PATERSON and J. G. GREENFIELD** (*Quart. Journ. Med.*, October, 1923, p. 6) describe the so-called "pink disease"—erythredema polyneuritis—with notes of five cases. Occurring between the ages of 4 months and 3½ years, an initial febrile coryza with slight bronchitis is followed by extreme mental misery and irritability, with insomnia and an obstinate anorexia leading to loss of weight. At the same time the rash appears as a diffuse erythema, most marked on the hands, feet, cheeks, nose, and forehead, which become red and swollen, with the appearance of oedema, but without pitting. There is marked perspiration of a mouse-like odour, and the hair falls out. There is no actual paralysis, but there is great muscular hypotonia with loss of tendon reflexes and anaesthesia over the extremities. The disease affects males slightly more than females, and the poor and well-to-do alike, and it has a widespread geographical and climatic distribution. While not appearing to be a deficiency disease, or due to food poisoning, or infection by the liphtheria bacillus, it seems to occur more frequently during and after influenza epidemics. In two cases examined *post mortem* the microscopic changes showed peripheral neuritis with chronic inflammatory changes in the spinal cord and nerve roots, the sensory nerve fibres being affected more than the motor. The prognosis is good, and unless the patient lies from asthenia due to anorexia or from complications complete recovery takes place in from three to nine months. Treatment is mainly symptomatic, to overcome the anorexia by careful nursing and the insomnia with hypnotics; small doses of arsenic and strychnine are beneficial.

**338. The Prognostic Value of Serum Phenomena in Diphtheria.**  
**J. W. RONALDSON** (*Brit. Journ. Child. Dis.*, July-September, 1923, p. 129), in his Glasgow M.D. thesis, points out that the prognostic importance of serum phenomena in diphtheria, which was first emphasized by J. D. Rolleston in 1904, has not received the attention it deserves. He gives tables showing that in spite of the enormous doses used the incidence of serum phenomena in very severe cases of liphtheria is less than in the milder forms, even after exclusion of cases which terminated fatally before the usual time of appearance of the serum rash. While there is no doubt that increased dosage raises the incidence of serum manifestations, diphtheria toxin exercises an inhibitory influence both on their frequency and intensity. In very severe cases of diphtheria the serum rash is late in development, scanty or entirely absent, whereas a serum reaction of any kind is greatly in favour of the patient. Even a few spots round the site of injection may give grounds for hope, while a well marked urticarial eruption is an excellent prognostic. The occurrence of a secondary rash, which is often accompanied by joint pains and pyrexia, is a still more favourable sign, a severe type of paralysis being very unusual in such cases.

**339. Thyroid Medication in Pruritus Genitalis.**  
**A. BREGMANN** (*Schweiz. med. Woch.*, August 23rd, 1923, p. 801) notes that there are certain cases of pruritus genitalis in which it is impossible to find any local or general disease to account for it. He suggests that in such obscure cases the glands of internal secretion may be to blame, notably the ovaries and thyroid. In support of this hypothesis he refers to three cases in which thyroid medication was remarkably effective. The patients were women between the ages 37 and 39, and the pruritus genitalis from which they suffered had been very troublesome for several months and had failed to respond satisfactorily to conventional local treatment. Narcotics had also been given, but without permanent benefit. Treatment with dried thyroid substance was instituted, the gland being obtained direct from a slaughterhouse, and 1.1 gram of the dried substance being given every day. The symptoms were less troublesome within a week, and after two weeks they had disappeared completely. The pruritus gradually returned after this treatment had been discontinued for two to three weeks, and when it was resumed the symptoms ceased again in a few days. It was found that only 0.05 gram of dried thyroid substance given daily was sufficient to prevent the return of the disease, which came and went with the discontinuance and resumption of the thyroid medication.

**340. Mercurial Poisoning from a Freckle Cream.**  
**A. ALEXANDER and K. MENDEL** (*Deut. med. Woch.*, August 3rd, 1923, p. 1021) record the case of a woman, aged 40, who was in the habit of using a mercurial ointment for freckles. She went from one physician to another complaining of headache and pain in the back, dragging pains in the limbs, diarrhoea with tenesmus, insomnia, and general debility. The diagnoses varied from rheumatism to neurasthenia, hysteria, and endocrine disturbances. The urine contained no albumin or sugar, but there were traces of mercury. The ointment was at last suspected, and it was calculated that she must have rubbed in about 0.17 gram of precipitated mercury daily, and that in the course of six years she must have used about 360 grams. The ointment was discontinued and aperients were prescribed, together with sulphur and electrical baths. Three weeks later the patient was considerably better, the urine no longer contained mercury, and the headaches and pains in the limbs had diminished much. This improvement continued during the following months, and fifteen months after the ointment had been discontinued she again felt physically quite well, but her mental vitality was still somewhat reduced. The freckles from which she had been wont to suffer, and for which she had taken the mercurial ointment, no longer troubled her. The author cites this case as a warning example of the harm that may be done when chemists repeatedly renew prescriptions without any medical control.

**341. Acute Suprarenal Insufficiency.**  
**N. J. SCHIERBECK** (*Hospitalstidende*, August 8th, 1923, p. 557) records in detail two fatal cases of acute suprarenal insufficiency. The signs and symptoms in these cases were remarkably uniform. In both there was abdominal pain with diffuse tenderness in the lower abdomen, a small soft pulse, an appearance of profound toxæmia, cyanosis and coldness of the limbs. In neither case was the correct diagnosis made before death. In both cases it might have been made had the blood pressure and sugar content of the blood been investigated, and in one case, at any rate, the patient might have been aided over the crisis of a laparotomy and general anaesthetic had the correct diagnosis been made and injections of adrenaline been given. In both cases extensive caseation of the suprarenals was found, and in neither were signs of severe tuberculosis found elsewhere. As the author points out, Emile Sergent of Paris has been teaching since 1898 that acute suprarenal insufficiency is a definite morbid entity which deserves recognition and the knowledge of which will explain many an obscure case characterized by the sudden onset of lassitude, general malaise, headache, abdominal pain, vomiting, a small and soft pulse, a low blood pressure, hypoglycaemia with (in some cases) diarrhoea, hypothermia, convulsions, and loss of consciousness.

**342. Sodium Citrate as a Vascular Drug.**  
**L. CHEINISSE** (*Arch. de med., cir. y esp.*, September 1st, 1923, p. 410) remarks that sodium citrate is employed not only for facilitating transfusion of blood, but is also of value in arteritis obliterans, intermittent claudication, Raynaud's disease, and congestive conditions due to the menopause. In Buerger's disease or thrombo-angiitis obliterans intravenous injections of 250 c.cm. of a 2 per cent. solution of sodium citrate are given, at first daily, and after a month every three or four days. In six cases so treated by Steel recovery took place after 50, 85, 69, 15, 48, and 30 injections respectively. Although complete functional recovery cannot be expected when advanced gangrenous lesions are present, the intravenous injection of sodium citrate relieves pain, checks the progress of the gangrene, and produces a spontaneous elimination of the necrosis and a cure of torpid ulceration. The drug can also be given successfully by the mouth provided large doses are administered and the treatment is continued for a sufficiently long period. A dose of 3 to 4 grams a day is the minimum that can usefully be given in severe cases. Ozo's patient received 1 gram every two hours. Until recently sodium citrate was chiefly employed to prevent coagulation, but Neulof and Hirschfeld of New York have advocated it as a haemostatic. It is only when there is an excess of citrate in relation to a given quantity of blood that suspension of coagulation takes place. Intramuscular injection of a 30 per cent. solution of sodium citrate sterilized in the autoclave in doses of 30 c.cm. (or of 15 c.cm. into each buttock), preceded by an injection of novocain, has proved

useful in internal haemorrhage, including haematemesis, traumatic haemothorax, haemoptysis, traumatic rupture of the liver, and in haemorrhages following operations on the rectum, bile ducts, compound fractures, and the like. Owing to its destructive action on the blood platelets sodium citrate is contraindicated in conditions accompanied by deficiency of platelets, especially haemophilia and purpura. Moreover, owing to its tendency to cause a greater fragility of the red corpuscles, it is also contraindicated in haemolytic conditions such as pernicious anaemia.

### 333. *Bacillus acidophilus* Milk.

H. A. CHEPLIN, C. D. POST, and J. R. WISEMAN (*Boston Med. and Surg. Journ.*, September 20th, 1923, p. 405), from investigations into the therapeutic effects of *B. acidophilus* milk in toxic intestinal conditions, show its value when implanted in the alimentary canal as the dominant organism by the oral administration of the milk culture in proper amounts. The bacillus, while it does not produce gases or toxins, suppresses *B. coli* and inhibits such toxicogenic microbes as the enterococci, *B. welchii*, *proteus*, and *putrificus*. Experimental evidence in nine cases established its beneficial influence upon constipation, diarrhoea, and mucous colitis, toxic symptoms being relieved with the regulation of the bowels and disappearance of mucus. The *acidophilus* milk was prepared by the method of Cheplin and Rettger, living 24 to 36 hour cultures being administered daily in addition to the ordinary diet, 1,000 c.c.m. of the milk culture with 50 to 100 grams of lactose being ingested in three equal doses two to three hours after meals. It is essential that a minimum averaging 50 billions of viable organisms should be given daily for at least six weeks, and it must be borne in mind that the ingestion of relatively few bacilli will not lead to implantation and bodily improvement, and administration in tablet form is useless. While it is not claimed as suitable for every gastro-intestinal disturbance, careful acidophilization of the enteric tract by means of *B. acidophilus* milk is recommended as a valuable means of therapy in toxic intestinal conditions.

## Surgery.

### 334. Vaccine Treatment of Chronic Osteomyelitis.

T. ROVSING (*Hospitaltidende*, August 8th, 1923, p. 563) has treated 23 cases of chronic or relapsing osteomyelitis with vaccines since 1915. In 16 of these cases the infecting organism was the *Staphylococcus aureus*. In the remaining cases *Staphylococcus albus* or the typhoid or paratyphoid bacillus was found. In the overwhelming majority of cases a surprisingly rapid improvement was effected, a complete cure being achieved even in cases which had persisted for ten or twenty years. With regard to the choice of vaccine, the author considers a stock vaccine definitely inferior to an autogenous vaccine, but in some cases the former has to be resorted to. When the osteomyelitis is complicated by sequestra these should be removed by the surgeon, but in none of the author's cases was the osteomyelitis thus complicated. Although he is enthusiastically in favour of autogenous vaccine treatment in the chronic or relapsing stage of the disease, he is very doubtful as to the value of this treatment in the acute stage; for in this stage the violent and localized infection does irreparable damage in a few hours, and vaccines do not act rapidly enough to check the disease in this virulent phase. All the three cases in which the typhoid or paratyphoid bacillus was found responded well to treatment with autogenous vaccines, although in one of these cases the osteomyelitis had persisted for over twenty years.

### 335. Pylorotomy in Gastric Ulcer.

M. MADLENER (*Zentralbl. f. Chir.*, August 25th, 1923, p. 1313) has obtained good results by pylorotomy in three cases of gastric ulcer in which the lesion was situated some distance from the pylorus. The ulcers were not excised, but in addition to the pylorus a portion of the duodenum 1 to 2 cm. in width and a small part of the antrum were removed. The duodenal stump was then anastomosed to the stomach. The ages of the patients, who were all women, were 45, 48, and 49. In all three cases pylorotomy was followed by a reduction of gastric acidity. In the first the diminution was slight; in the second the free acidity fell to a quarter of its original value; and in the third complete anacidity resulted. The change in the gastric chemistry is closely associated with a change in motility, there being a considerable delay in the evacuation of the gastric contents for some weeks after the operation. Madlener points out that the view is no longer held that gastric or duodenal ulcer is cured by excision. Although the ulcer is removed, the disease, or rather tendency

to the formation of gastric ulcer, persists, for which there is no certain remedy. The best treatment, however, consists in producing a complete change in the secretory mechanism of the stomach by removal of the pylorus. As a rule, this change is well tolerated, and it is found that the pylorus, though not ulcerated, has become hypertrophic as the result of spasm and is the site of chronic gastritis.

### 336. Myelitis following Genito-urinary Infection.

F. P. CURRIER (*Journ. of Nerv. and Mental Dis.*, September, 1923, p. 201), describes three cases seen in the neurological clinic of the University of Michigan, in which patients suffering from an infection of the genito-urinary tract developed, after operation, symptoms pointing to an involvement of the central nervous system. In the first two cases the condition developed within a few days of operation, but in the third case the onset was delayed for a period of two months, during which daily bladder irrigations were carried out. Briefly, the symptoms were those of a transverse myelitis, and included pain or numbness in the lower limbs, followed by slight paresis and a varying degree of alteration in the motor and sensory reflexes in the region affected; in one instance there was pain over the bladder and frequency of micturition. The infection appeared to be of a mild type, with a tendency to recovery, and pain and paresis were never severe. The site of the pain localized the lesion to the sacral and lumbar regions of the cord, and, as this is the section from which the genito-urinary system derives its nerve supply, the author, whilst admitting absence of definite proof, assumes that infection travelled directly along the nerves to the meninges of the cord, later involving the cord itself. The cases are presented in support of similar views expressed by previous observers, whose findings are quoted.

### 337. High-frequency Treatment in Internal Cicatricial Strictures.

H. PICARD (*Klinische Wochenschrift*, September 24th, 1923, p. 1796) recommends heat treatment or diathermy, produced by high-frequency currents, in the treatment of cicatricial strictures of the oesophagus, urethra, and rectum. By diathermic treatment anemic, hard, inelastic scar tissue becomes vascular, soft, and elastic; the author has applied this treatment to the internal strictures just named. In the case of the oesophagus an elastic metal bougie was used as the internal electrode, and the other indifferent electrode was a plate on the chest or back at the level of the stricture (technical details are given). Three cases of oesophageal strictures are recorded in which excellent results were obtained. Also in two cases of urethral stricture in which the treatment was tried good results were obtained. Strictures of the rectum of syphilitic or gonorrhoeal origin are especially suitable for treatment by this method (the internal electrode is introduced into the rectum, the indifferent electrode is placed on the abdomen and back). Two very successful cases are recorded. Though recurrence of symptoms may occur later the temporary results have been very satisfactory, and the author thinks a further trial of the treatment should be made.

### 338. Splenectomy in Chronic Thrombocytopenia Purpura Haemorrhagica.

N. E. BRILL and N. ROSENTHAL (*Amer. Journ. Med. Sci.*, October, 1923, p. 503) advocate the treatment by splenectomy of chronic thrombocytopenic purpura haemorrhagica. Symptomatically the disease is characterized by cutaneous petechiae, and purpuric and ecchymotic spots, accompanied by haemorrhages from the gums, nose, intestines, and kidneys, owing to the vulnerability of the capillaries. The bleeding may be intermittent or continuous, gradually exsanguinating the patient. Though found chiefly in youth, it may occur at any age, and it is not hereditary. An acute attack may be fatal in a few days or disappear after two or three weeks, or it may become subacute or chronic, with bleeding from the nose and gums which resists all attempts at stopping. The blood shows a marked diminution or even absence of platelets (thrombocytes), and though the clotting time is normal the clot does not shrink, while the bleeding time is prolonged to more than ten minutes. In two cases, a boy and a girl, suffering from the chronic intermittent type, splenectomy was performed with excellent results, the immediate effects of operation being cessation of bleeding from all mucous surfaces and a rapid increase in the number of platelets—from 6,000 to 270,000 per cubic millimetre in one case, and from 400 to 60,000 in the other. Although thrombocytopenia may return, the capillary bleeding remains cured, possibly from the removal of a toxin manufactured by the disordered spleen which interfered with the tonus function of the endothelial capillary cells. The disease appears to be an involvement chiefly of the spleen and bone marrow, and the results of splenectomy will

The patient, Mr. S., a powerfully built man of 23, was returning home on his motor cycle about midnight on September 25th, 1923, when he met with an accident. Exactly what happened the patient himself could not tell, but he thinks that his lamp went out, that his machine struck a bank at the side of the road, and that he was heavily thrown. He managed to crawl to a neighbouring house, where he was kept till the following morning, when he was conveyed to his lodgings about twelve miles away. He was seen shortly after his arrival by C. R. T., and though he was apparently quite unconscious at that time, the patient stated that his mind was an absolute blank from the moment of the accident until the following afternoon. A careful examination by C. R. T. failed to reveal anything more than severe bruising of the back, chiefly in the neighbourhood of the left iliac crest. After examination he walked to his father's house, some hundreds of yards away. He was kept in bed and visited daily and there seemed to be very little the matter with him.

At 1 a.m. on September 9th, in response to an urgent summons, C. R. T. visited him and found him suffering from very severe abdominal pain: pulse 120, temperature 101°. The abdomen was

The following case has seemed to us worthy of placing on record on account of the unusual features which it presented.

may be compared to a gesture, slight but ominous, and full of menace.

[illegible]

probably be better in those cases in which the spleen is very large than in those with smaller spleens. The operation is a life-saving measure in grave cases, and evidence points to its being curative. Although transfusion is useless in treatment, it is wise for this to be done before and after operation as a means of avoiding further loss at operation, and of preventing shock afterwards.

### 349. Simple Ulceration of the Small Intestine.

M. CHABRUT (*Paris méd.*, August 11th, 1923, p. 124), who records two cases in women aged 25 and 54, states that simple ulceration of the small intestine is hardly ever recognized until perforation occurs, and in almost every case the perforation gives rise to general peritonitis. In 17 cases of simple ulcer of the small intestine collected by Combes, the jejunum was affected in 7 and the ileum in 10. Léotta could find only 22 undoubted examples of the condition on record, and in every case but one, in which the ulcer was not discovered until the autopsy, general peritonitis was present. On the other hand, Bergeret has described a case in which, sixteen hours after the onset, adhesions were found between the intestinal coils sealing up the perforation. In the two cases recorded by Chabrut the ulcers were certainly not due to a new growth, nor was there any evidence of syphilis or tuberculosis, but both the patients developed the symptoms suddenly in the midst of apparently perfect health. Recovery took place in both cases after operation, at which a localized pelvic peritonitis was found, due to perforation of an ulcer in the ileum.

### 350. Haemorrhage in Nephrotomy.

B. FET (*Paris méd.*, August 4th, 1923, p. 105) distinguishes the following three varieties of haemorrhage connected with nephrotomy: (1) haemorrhage in the course of the operation due to incision of the kidney substance; (2) primary haemorrhage due to inadequate haemostasis; (3) secondary haemorrhage, of which the cause is obscure, but probably connected with the production of infarcts in the nephrotomized kidney. This form of haemorrhage is much the most important and most difficult to control. Haemorrhages occurring in the course of the operation are controlled first by making the incision in the so-called bloodless zone, which corresponds to a line passing 1 cm. behind the outer border of the kidney; and, secondly, by a temporary haemostasis which is effected by compression of the renal pedicle. After removal of the renal calculus temporary haemostasis should be replaced by a permanent one. Haematuria is constant for the first two or three days after nephrotomy and ceases on the fourth or fifth day, but in some cases it becomes much more profuse so as to endanger the patient's life. A permanent haemostasis should therefore be carefully carried out at the end of the operation by an exact apposition of the lips of the incision with catgut sutures. Legueu has found that all kidneys which had been excised for secondary haemorrhage after nephrotomy showed an infarct round which most of the haemorrhagic lesions were situated. It is probable, therefore, that an infarct plays a part in the production of secondary haemorrhage, though the exact mechanism is obscure. The prevention of infarction should be carried out by making the incision in the bloodless zone and avoiding rupture of anomalous arteries on removal of the kidney outside the wound. When once secondary haemorrhage has occurred the only effective treatment is nephrectomy, although naturally the ordinary methods of controlling haemorrhage must be first tried.

### 351. Hernia in Children.

CRAGLIETTO (*La Pediatria*, October 1st, 1923, p. 1041) publishes his experience in the treatment of hernia in children. He has operated on 582 children (625 operations), of whom 515 were male and 67 female; the hernia was strangulated in 8 cases; 64 children were under 1 year of age. He points out the advisability of watching the children some few days before operation, in case they might be developing some other malady. He used chloroform almost exclusively as the anaesthetic, as he found ether too irritating. In only one case could serious symptoms be attributed to chloroform. Later he has used pure alcohol (95 per cent.) as a disinfectant in preference to iodine. Unless there is uncertainty as to the contents of the sac he does not open it. Exceptionally he found the testis in one sac, and in 3 cases military tubercle was freely deposited on the sac wall. All the cases healed by primary intention except 5. The total mortality was 4, and in 2 of these death was not due to the operation. The hernia was umbilical in 13, ventral in 1, and epigastric in 1. Relapse was only noted in one child of 5½ years who had been operated on four years previously. Whilst the author does not deny that some cases are cured by a truss, he is strongly of the opinion that, unless contraindications are present, radical cure is the best course.

## Obstetrics and Gynaecology.

### 352. Bacterial Infection of the Urinary Tract complicating Pregnancy and the Puerperium.

FROM a series of 34 cases of urinary infection, which could be classed clinically as pyelitis, J. HEWITT (*Journ. Gyn. and Obst. Brit. Empire*, vol. 30, No. 3, Autumn, 1923, p. 390) draws the following conclusions: The acute type of pyelitis, though often misdiagnosed for some time owing to the resemblance of the symptoms to appendicitis, malaria, influenza, etc., and the unobtrusiveness of the bladder symptoms, is always treated as a serious case, as the woman is definitely ill; but this is not so in the chronic type, which often passes unrecognized for a long period, the patient's only complaint being backache and slight frequency of micturition, often preceded by headache and malaise for a week or two. Albuminuria is only present in the acute cases. Coliform organisms are present in over 90 per cent. of cases, but, as Leith Murray says, must not be taken as diagnostic of the disease without the presence of pus. According to the author the diagnosis can be made for certain only by finding pus cells and organisms in a single drop of uncentrifuged urine. As regards treatment, hexamine combined with acid sodium phosphate was first tried, with very unsatisfactory results, pregnancy being interrupted in 11 out of 19 cases. The author therefore advises the alkaline treatment, first recommended by Frank Kidd, and gives sodium bicarbonate 60 grains with potassium citrate 20 grains every two hours for several days, and then every four hours, the patient being encouraged to drink plenty of fluid as well. With this treatment pain is relieved even in the acute cases in thirty-six to forty-eight hours, and the pulse and temperature usually become normal in about four days. The pus is diminished markedly by the alkali treatment, but bacilluria persists, and this is treated in about fourteen days' time by the hexamine treatment. It is important not to begin this latter treatment until all symptoms have disappeared and the pulse and temperature have been normal for some time, otherwise exacerbations of the disease are apt to occur and death has even been known to take place owing to a too early administration of the hexamine. The patient is kept on the latter treatment for the duration of the pregnancy to prevent recurrences, which are liable to occur either in the same pregnancy or in succeeding ones. With this treatment 14 cases out of 15 went to full term. If hexamine fails to prevent a recurrence, which may happen, the combination with an autogenous vaccine is advocated.

### 353. Venesection in Pre-eclamptic Conditions.

A. J. POWILEWICZ (*Journ. de Méd. et de Chir. Prat.*, October 10th, 1923, p. 609) remarks that bleeding, universally employed in the treatment of eclampsia, and even of its antecedent toxæmic manifestations, during the eighteenth century, was almost abandoned during the course of the ensuing hundred years. Nevertheless venesection, if properly controlled by measurement of the arterial blood pressure, constitutes a valuable mode of treatment, and one which is practically free from danger, in cases of pre-eclamptic toxæmia with hyperplasia. The blood should be taken away slowly to permit of vasomotor readjustment. At the Baudelocque Clinic the blood pressure is taken repeatedly in every pregnant or parturient patient who shows albuminuria or suffers from oedema or other pre-eclamptic sign of toxæmia; a tension of 200 mm. or more is regarded as an indication for venesection, the mean amount abstracted being 600 to 800 grams. In one series of 92 cases of albuminuria, of which 13 were associated with a notable hypertension, four patients had a blood pressure of over 200 mm. and were bled; none of the series suffered from convulsions. It is necessary to watch the patient carefully for some time after venesection; a further rise of arterial tension may necessitate a second bleeding, and in an occasional case the patient after labour, especially if this be attended with much haemorrhage, may suffer from syncope attacks.

### 354. The Importance of a Bacteriological Examination after a Febrile Abortion.

O. MEHL (*Schweiz. med. Woch.*, September 6th, 1923, p. 842) publishes statistics in support of his thesis that the choice between conservative and operative treatment in cases of febrile abortion should depend on the findings of a bacteriological examination of the contents of the uterus. He argues that when this examination fails to reveal streptococci or staphylococci which liquefy gelatin, it is safe to remove at once the contents of the uterus. Such removal tends to hasten recovery. Should, however, the germs already referred to be found within the uterus in a case of abortion

[illegible]

associated with fever, only conservative treatment should at first be adopted. The material on which he bases these opinions is partly obtained from the University Gynaecological Hospital in Zürich, where for some time the practice has been adopted of making a bacteriological examination of the contents of the uterus after a febrile abortion. Of the 55 cases of streptococcal abortion at this hospital conducted on conservative lines, not one terminated fatally. A study of the literature of such cases yielded information definitely in favour of the author's views. In one table he has collected the records of 252 cases of streptococcal abortion treated by operative means, and showing as high a mortality rate as 13.1 per cent. On the other hand, the mortality was only 2.6 per cent. among the 1,159 streptococcal abortions treated by conservative methods. The lesson of these observations is that so long as a streptococcal or staphylococcal (staphylococci liquefying gelatin) abortion is associated with fever, the use of a curette greatly increases the chances of a fatal issue.

### 355. Treatment of Hyperemesis Gravidarum.

LÉVY-SOLAL (*Journ. de Méd. et de Chir. Prat.*, October 10th, 1923, p. 685) remarks that in the absence of a specific mode of treatment remedial measures in hyperemesis gravidarum must be directed against (1) the toxæmia due to hepatic and endocrine disturbance, (2) the inanition and the acidosis provoked by the vomiting, and (3) the neuropathic state of the patient. (1) A diet of milk and vegetables should be tried, but if not tolerated milk or water should be given alone for twenty-four to thirty-six hours. Extracts of corpus luteum or of its lipoids (2 cc. of extract of corpus luteum in 1 c.c.m. of physiological saline solution saturated with chloretone, injected every other day) and adrenaline in doses of 30 to 50 drops by the mouth have been given with some apparent success in the endeavour to rectify the disturbance of the ductless glands. (2) Acting on the view that the diminished carbohydrate intake associated with the persistent vomiting plays a secondary part in maintaining the acidosis, and therefore the nausea and the vomiting, Weill and Landat recommend rectal administration of 5 per cent. solution of glucose in blood serum. (3) Psychotherapeutic measures adapted to each particular case may be combined with rectal injections of 4 grams of chloral hydrate together with 100 grams of milk per diem. If these measures fail it is important not to defer for too long the moment at which abortion has to be induced. The indications for this are, first and chiefly, irregularity, hypertension, and persistent frequency (at 100 or more a minute) of the pulse; secondly, toxæmic manifestations, such as slight jaundice, dyspnoea, or psychic disturbances.

## Pathology.

### 356. The Etiology of Chorea.

THAT chorea is due to a streptococcus possessing characteristic properties, among which is a selective action on the nervous system, is the opinion of E. C. ROSENOW (*Am. Journ. Dis. of Children*, September, 1923, p. 223). As early as 1910 this observer found that the disease developed in a dog and a rabbit following intravenous injection of a streptococcus isolated from the blood of a fatal case of chorea. Both animals contracted a low grade meningitis; the rabbit, further, had lesions of the joints, and the streptococcus was recovered in pure culture from the cerebrospinal fluid. Similar results were obtained on four widely separated occasions after intravenous injection of a series of animals with cultures from tonsils during the acute stage of chorea, and again chorea-like symptoms, with lesions of the joints, muscles, and heart, were found in animals injected with the organism isolated from the joint fluid, blood, or infection focus of patients suffering from acute rheumatic fever. In recent experiments, using cultures of pus from the tonsils and exudate from the nasopharynx of cases of chorea, the same observer has found it possible to demonstrate that characteristic symptoms and localization of lesions (as seen at autopsy) are even more definitely obtained by intracerebral inoculation in rabbits, and, in dogs, by sealing up a dense suspension of the organism in the pulp canals of the teeth. The property on which localization depended was retained through three successive animal passages, after repeated rapidly made transfers of pure cultures, and up to three months in the teeth and brain of dogs. The symptoms produced showed a most marked similarity to those of chorea in human subjects, and the lesions in the central nervous system resembled in type and distribution those of man, being found principally adjacent to or within motor centres or motor tracts in the cerebrum, mid-brain, or cerebellum.

Again, in extent and location the lesions frequently corresponded to the severity and type of the symptoms during life. On necropsy, the lesions of the heart valves, their location and histological appearances, were those of chorea in man. The organism, which was absent in normal tissues, was seen in numbers in or near the experimental lesions. These findings were checked by control experiments, similarly performed, with cultures of organisms isolated from cases of encephalitis, epidemic hiccup, ulcer of the stomach, and from the throats of normal persons and those suffering from poliomyelitis. It was found that in the control experiments localization rarely occurred in the heart valves, joints, or muscles, nor were the symptoms produced similar to those following injection of strains of chorea. The particular streptococcus giving the above results in animal experiment occurs as a diplococcus forming chains of medium length. It is free from both as regards... was destroyed by cultivation under aerobic conditions.

### 357. The Action of Tuberculin made from various Acid-fast Bacilli.

E. LANGE (*Zeit. f. Tuberk.*, Bd. 38, Hft. 5, 1923, p. 334) has prepared tuberculin from various acid-fast bacilli, some of which were innocuous, saprophytic germs, and he has given intracutaneous injections of these tuberculin to fifty persons suffering from tuberculosis. The reactions to the different tuberculin were, on the whole, remarkably uniform, and the author suggests that the response of the tuberculous patient to the introduction of a variety of tuberculin into the skin is practically the same, whether the tuberculin are derived from pathogenic or innocuous acid-fast germs.

### 358. Does the Formation of Gall Stones depend on Infection?

T. ROYSING (*Acta Chir. Scand.*, September 4th, 1923, p. 163) answers this question in the negative, although, according to the teaching of Naunyn and his followers, the formation of every gall stone depends on an infection of the gall bladder. For the past thirty years the author has systematically examined every one of his 530 cases of gall stones coming to operation, withdrawing the contents of the bladder and (in some cases) excising part of its walls for a bacteriological examination. The contents of the gall bladder proved to be sterile in 314 cases (59.3 per cent.) and infected in 216 cases (40.7 per cent.). It has been suggested that an originally infected gall bladder may become sterile, the germs being locked up within the gall stones. Recently the author has undertaken bacteriological examinations of the interior of gall stones, but he has never found germs within them in cases in which the bile was sterile. The relative frequency of sterile and infected cases was practically the same when the cases were classified according to the nature of the gall stones. The author concludes that infection of the gall bladder is a complication and not a cause of gall stones, and he compares the condition of the gall bladder with that in the urinary bladder when it contains a calculus. No case has yet been recorded in which an infected bladder became sterile so long as a calculus remained in it, and this observation shows what an important factor stones are in maintaining sepsis. The evidence of the clinician is also in favour of the author's unbelief in gall stones being due to infection of the gall bladder; typical cases of cholelithiasis may be completely afebrile for several years and then suddenly show signs of sepsis, such as rigors and fever.

### 359. The Blood Picture in German Measles.

J. KANEKO (*Journ. Oriental Med.*, August, 1923, p. 112) examined the blood of 46 children suffering from rubella in the children's clinic at the Daien Hospital in South Manchuria. Unfortunately little is said about the age of the patients, and remembering the inconstancy of the blood picture in infants it is necessary to accept his findings with some reserve. The red blood cells and the percentage of haemoglobin were found to be normal. On the other hand, there was a slight leucopenia, most pronounced in the eruptive stage, and continuing for about a week. The highest white cell count was 7,900 and the lowest 5,600 per c.mm. For this diminution the polymorphs were responsible, their percentage being diminished to between 30 and 45. The lymphocytes were correspondingly increased, there being but little alteration in the other white cells. An examination of the polymorphs for the presence of Doehle's granulations showed that these were not so frequently encountered as in the other exanthemata, and even when such granulations were to be found the proportion of cells showing them was rather low.

The myotonia of the nervous child is not confined to skeletal muscles. It clearly involves also the muscles of heart and of the blood vessels. Complaint is often of pallor, constant or intermittent. After excitement or exertion, specially when the body has been upright for length of time, the blood is prone to fall away from surface of the body, leaving the face pale and drawn.

As a result of this vaso-motor anæmia the face has imprinted upon it a look of ill health which not only alarms the mother but provokes comments from her friends and relatives. The subjective sensations of the child clearly vary with the circulatory reactions in the skin, and when the pallor is extreme complaint is usually made that the child lies about listless is without appetite and appears depressed or fearful.

### Albuminuria.

A postural or lordotic albuminuria is frequently for if routine examination of the urine is made. It seems to me in the highest degree unlikely that the lordosis of pressure upon the renal vein. I have been unable to substantiate the statement that by inducing lordosis means of a plaster jacket in a healthy child it is supposed to produce albuminuria even in the recumbent posture. It appears more reasonable to conclude that lordosis of albuminuria are alike symptoms of the failure of mechanism by which the force of gravity is counteracted. It is usual to find that the feet and hands are cold cyanosed.

### Abdominal Pain.

Complaint is often made of attacks of abdominal pain and sometimes of vomiting, synchronizing with the attacks of pallor and due generally to emotional excitement or fatigue. Now that operations for what is termed "child appendicitis" are frequently, it is not unusual to find that a child, complaining of these symptoms, shows fear of an appendicectomy operation. Syncopal attacks are other complaints which occur with great frequency in these children. If we encounter with their fatigued and unstable circulatory reactions, and observe them as suffering from "cardio-vascular asthenia" or "effort syndrome."

### Enteroptosis.

If, on the other hand, we are more impressed by a group of symptoms to which I shall refer, we shall see they grow to adult age become candidates for the operation of colectomy or coloprocty. With the passage of years and the permanent fixation of the postural defect, not difficult to demonstrate the increasing tendency of enteroptosis, due to the faulty postural reaction to gravity and especially to the peculiar lax and toneless abdominal musculature. Constipation is a frequent symptom, do not think we do a service to our understanding of condition by attributing either to the constipation the cardio-vascular asthenia a too great etiological importance.

### Proneness to Catarrh.

Further mention must be made of the low immunity which this type of child possesses against the catarrhal infections. Cold-catching children seem to be divisible into two groups: those in whom we find element of tonsils and adenoid vegetations, with chronic catarrhs, in whom the fault lies in the weakness of the nasopharynx; and children who continue to catch cold in spite of repeated operations upon nasopharynx, in whom the fault lies in the weakness of the paranasal defences. When the skin of a child is glistened and warm from exposure to wind and sun, colds are caught, but even a strong man is prone to contract catarrh when the respiratory tone has been weakened by whatever position they are put. Consequently, precision of limbs will stay passively for many minutes at a time in the power to initiate voluntary movements at all, and the child seems to have lost for the time being the desire or that of complete exhaustion, while the expression has been play has been very striking, the absence of facial forehead wrinkling and the fingers writhing and pinching, constant movement and overplay, the lips twitching, the hands which serve to express emotional states are in As a rule in these children the small muscles of the face noticeable.

which may deceive. With the young child this is never so. An effort square his shoulders and assume a comical air attention at the first glances. The nervous adult may by bearing, and posture of the nervous child which arrests particular defects there is something about the carrying, and apart from these

### The Amyotonia of Nervous Exhaustion.

In most nervous children a want of tone in the skeletal muscles is so prominent a feature that a characteristic stance and posture result. The amyotonia affects especially upright position and whose tone is consequently at work to counteract the action of gravity. Sherrington has shown that certain muscle groups especially serve this specific purpose. The stance of the nervous child may be described as the opposite of that which the drill sergeant inculcates so vigorously in the recruit, and it is to be noted that although the routine of drill at first appears to aim at a purely physical effect, experience shows that by achieving a condition of greater provision of movement, the recruit acquires what is more important—courtesy, promptitude, and presence of mind. As the recruit stands, the head is held erect, the chest is expanded, the abdomen is retracted, the feet are closely together and the body is inclined a little forward so that a vertical from the centre of gravity falls in front of the feet.

The stance of the timid and nervously exhausted child provides the contrast to this ramodal and curative posture adopted in drill. The trunk is not braced by the muscles of the back. The weight is rather balanced upon the stance than supported by muscular tone. The feet tend to be separated. The shoulders are carried far back so as to bring the centre of gravity directly above the feet. Therefore the centre of gravity, as in the amyotonia of a primary muscular dystrophy, is a considerable degree of lordosis, while a secondary and compensatory curve in the cervical region becomes necessary to bring head and eyes forward into line. As a result of the lordosis the abdomen is pushed forward into undue prominence while the chest recedes. Similarly the amyotonia of the shoulder muscles allows the weight of the dependent parts of the shoulders and to separate the scapulae and to exert their inner border. Movement is often awkward and inco-ordinate, and a too great tendency to tumblers is a frequent complaint of the dystrophers. As in the young child the weakness of the supporting muscles, appears as a support which is maintained by balancing the weight upon the substituted support of muscular contraction a support of the "antigravity" muscles, appears designed to fall. This posture, resulting from the weakness or exhaustion of the spine, even so the maintenance of position against any support which offers—a wall, the table, their mother. They are constantly being urged to stand erect or to sit upright. The taller the child, the more striking is this failure to accommodate to the upright position. Under the age of 6 the lordosis is seldom very noticeable.

As a rule in these children the small muscles of the face noticeable. In some of the worst cases, however, the expression has been that of complete exhaustion, while the expression has been play has been very striking, the absence of facial forehead wrinkling and the fingers writhing and pinching, constant movement and overplay, the lips twitching, the hands which serve to express emotional states are in As a rule in these children the small muscles of the face noticeable. Under the age of 6 the lordosis is seldom very noticeable.

## A British Medical Association Lecture

OR

## THE PATHOLOGY OF GASTRIC ULCER.

DELIVERED TO THE DERBY DIVISION, MAY 18TH, 1923,

BY

MATTHEW J. STEWART, M.B., Ch.B., M.R.C.P.,

PROFESSOR OF PATHOLOGY, UNIVERSITY OF LEEDS.

## PART I.—THE ETIOLOGY OF PEPTIC ULCER.

It is now generally believed, on strong clinical and pathological evidence (Bolton, 1913<sup>1</sup>), that all chronic gastric ulcers arise in and from acute ulcers—that is, that all ulcers are rapidly formed in the first instance, a chronic ulcer being merely one which has been in existence for a certain length of time. Two etiological problems are thus presented—(A) the cause or causes of acute ulcer, and (B) the factors which lead to the persistence or non-healing of such an ulcer.

## A. ETIOLOGY OF ACUTE ULCER.

The various factors, clinical and experimental, concerned in the production of acute ulcers fall into two categories: (1) those which act by producing injury (malnutrition, devitalization, etc.) of the gastric mucosa, and (2) the digestive action of the gastric juice.

## 1. Causes which Act by Damaging the Mucosa.

Experimentally, injury to the mucosa of such a kind as to lead to ulcer may be brought about in a great variety of ways. Clinically, also, many possible causes have to be taken into account. Whatever the agent, the most frequent mechanism appears to be by the production of a focus of necrosis, with or without a preceding focal haemorrhage, or the lesion starts as an inflammation of the lymphoid follicles.

(a) The theory of vascular blocking was one of the earliest to be put forward, and was a deduction by Virchow from the well known funnel-shaped character of many gastric ulcers. Such blocking might result from arterial embolism or venous thrombosis, with or without pre-existing disease of the vessel wall, but neither clinically nor experimentally is there any considerable body of evidence in support of this. The anastomotic connexions of the large and medium sized arteries of the stomach are so extensive and complete that it is practically impossible to produce ulcer experimentally by obstructing one or even several of them. It is possible, however, to produce typical acute ulcers by injecting into a gastric artery substances which will produce embolism in the small arteries of the mucosa and submucosa—for example, fat (Schröder, 1907<sup>2</sup>), or a suspension of lead chromate (Cohnheim, 1890<sup>3</sup>). Clinically it is not found that sources of sterile emboli are commonly present in cases of gastric ulcer, nor is venous thrombosis often met with except as a secondary or terminal event.

Vascular obstruction or stasis may also be brought about by spasm of the arteries or of the stomach itself. Durante (1916)<sup>4</sup> produced ulcers by section of the vagus or sympathetic nerves, or both, and he attributed his results to arterial spasm, due, he believed, to excessive production of adrenaline, while the acute duodenal ulcers of experimental adrenaline intoxication (Friedman, 1915<sup>5</sup>) may have a similar explanation. There is no definite evidence that vasomotor spasm is a factor in the production of ulcer in man, although on clinical grounds there is much to be said for it. As Hurst (1922)<sup>6</sup> points out, "something of this kind would alone explain the undoubted influence of sudden change of temperature in the production of relapses of gastric and especially of duodenal ulcer, and the frequent association of a poor peripheral circulation with gastric and duodenal ulcer."

Spasmodic contraction of the stomach itself, on the other hand, is a well known and common accompaniment of chronic ulcer, and one which may well exert a vicious influence on the lesion. There is no proof, however, that it is a cause of ulcer in the first instance.

(b) General nutritional factors in the etiology of gastric ulcer are now largely discounted. Bolton emphasizes the fact that there is no reliable evidence to show that chlorosis is etiologically related to ulcer as was once thought, "neither is there any evidence to show that an acute ulcer spreads more readily in anaemic patients." The terminal acute ulcers occasionally met with in cachectic subjects can be much better accounted for by a terminal infective hypothesis.

(c) Trauma by chemical or by physical agents is an undoubted cause of gastric ulcer, but from its supposed infrequency is generally regarded as of little clinical importance. The swallowing of caustic substances—strong mineral acids, silver nitrate, and the like—may be followed by ulcer, and Bolton has emphasized the possible importance in this connexion of the dietetic use of vinegar, acetic acid being a powerful protoplasmic poison even in dilute solution (2 per cent.). Mechanical trauma, whether from within or from blows on the abdomen, is even less important. It is well known that the stomach will tolerate in a quite remarkable way the presence in its interior of hard foreign bodies, such as knives and nails, without becoming ulcerated. From time to time cases are reported—for example, the recent case of H. E. Griffiths (1922)<sup>7</sup>—in which there is apparently a very close connexion between a blow on the abdomen and the development of gastric ulcer, and one has seen lesions of the stomach (focal haemorrhages and lacerations) in cases of traumatic death which might well have been the starting point of ulcer had the patient survived.

Thermal trauma, scorching or scalding from hot food and drink, has had much importance attached to it by some writers. Decker (1887)<sup>8</sup> produced gastric ulcer in two dogs by feeding them on gruel at 62° C., while Heiser (1922)<sup>9</sup> found that in 103 gastric ulcer patients there were only four who were not notorious for insisting on their food and beverages being served very hot, or they were very rapid eaters, or both.

(d) Bacterial infection and intoxication is, however, undoubtedly the most important direct cause of acute gastric and duodenal ulcer in man, as it is the method by which, particularly in the hands of Rosenow, some of the most remarkable experimental results have been obtained. It has long been known that acute ulcer might occur during the course of acute bacterial infections, as well as in other forms of toxæmia, but it is only within recent years that the importance of this connexion has been fully established (Gandy, 1899,<sup>10</sup> and Bolton, 1913<sup>1</sup>).

I have analysed a series of 53 cases of acute gastric and duodenal ulceration met with in the course of 1,500 consecutive autopsies. In 2 cases only were the ulcers the proximate cause of death—one a man of 42 years of age who died of mesogastric and mediastinal cellulitis due to three acute linear ulcers near the cardiac orifice, the other an infant of 4 months who died of haemorrhage from multiple duodenal ulcers. In half the cases (27 out of 53) acute septic disease was present; peritonitis from various causes 14, bronchopneumonia 6, empyema 3, pyelonephritis 2, and pericarditis and meningitis one each. The principal causes of death in the remainder were cancer (6), cardio-vascular disease (6), tubercle (2), corrosive poisoning (2), and syphilis (1).

Many writers have stressed the importance of less serious, localized forms of infection, both in relation to the etiology of acute ulcer and as a cause of acute exacerbations in chronic ulcer. Dental and tonsillar infections, appendicitis and cholecystitis in particular, have been incriminated on strong clinical evidence.

The clinical connexion between non-bacterial forms of intoxication and ulcer is much less clear, although in animals positive results have been obtained by the injection of a large variety of substances (arsenious acid, chloroform, snake venom, bile salts, gastrotoxic serum, etc.). There is, however, one form of ulcer in man which probably belongs to this class—that which follows extensive burns.

In a series of 6,800 autopsies there were 115 subjects dead of burns, of whom 57 were 20 years of age or over. In this group 2 cases only showed ulceration of the stomach or duodenum. In a child of 5 who died thirty-three days after extensive burns of the trunk and limbs there was a small acute ulcer in the pyloric region of the stomach. In a man

FIG. 1.

FIG. 2.

FIG. 3.

Figs. 1, 2 and 3, illustrating the weakness of the "anterior" postural muscles which commonly accompany nervous exhaustion or instability in children. The axis of the head is in a vertical line above the neck, through which, rather than through the ball of the foot, the weight passes. The knees are hyperextended. There is a pronounced lumbar lordosis and a secondary forward curve in the upper dorsal and cervical regions. The thorax is flattened from before to behind, the shoulders are depressed, and the maximum degree, Figs. 2 and 3 to the extent which is commonly met with.

some great grief. The aspect of these frail and debilitated children is not unlike that which may result in all of us after some exceptional strain, and the vasomotor collapse carries with it an increased tendency to infection. Of the deleterious result of infection in nervous children I need not speak. Each new pyrexial attack leaves behind it a visible increase in restlessness, in exhaustion, and in muscular weakness. From such a child, not every possible, but every proved, source of infection should be eradicated.

*Irregular Temperature Curve.*  
Finally, I think there can be no doubt that it is in this type of child that we encounter a failure to achieve the monothermia of health. The skin temperature varies with the vascular reaction in the skin. When the child is pale and exhausted subnormal readings are the rule, but when flushed with excitement the reading often rises to 100° or even higher. An evening rise of temperature is not uncommon, and must not, I feel sure, be regarded as proof that the fear of consumption, so often aroused by the aspect of the child, is justified.

# THE ONSET OF PARTICULAR NERVOUS SYMPTOMS IN PARENTICULAR FAVORS OF PARENTICULAR CONTROL.

The study of the nervous child is to a great extent the study of his parents and of the powerful influences for good or evil which proceed from them to an unduly susceptible child. It is essential to realize the intimacy of the relationship between the mother's mind and the child's. However keenly interested we may be in the ailments of children as seen in hospital, and however skilled in their treatment, we shall fail altogether in the home if we do not appreciate or cannot control this influence of the mother which separates us from the child. In hospital we may learn much of the physical ailments peculiar to children; of functional nervous disturbances we shall see very little. The trained nurse, when she leaves the hospital and begins work in the home, finds herself faced with new and strange problems, and it is not surprising that her want of resource in dealing with them is sometimes plain to the mother and a subject of complaint against her. How frequently, for example, do we encounter an absolute and successful refusal on the part of the infant, for many days, to leave its mother's breast and to take food offered in cup, spoon, or bottle. In hospital this is commonly met with.

Consider first how open the young child is to suggestions of all sorts. He is quick to form ideas as to what is or is not characteristic of himself, yet at the same time he is without power of self-discrimination or self-analysis. He sees himself only in the eyes of his elders. Whatever is thought of him, said of him, even feared for him, that he rapidly becomes. The symptoms of functional nervous disturbance which are most rife among nervous children are those about which the mind of the ordinary mother is most preoccupied. They concern the sensitive digestive system and the urinary apparatus. Paralysis, anaesthesia, spasm are rare, and they are rare because it is not such disasters that are foreboded for the child. On the other hand, anorexia nervosa, nervous vomiting, pica, bulimia, polydipsia, constipation, nervous diarrhoea, neurasthenia, frequent micturition, and retention of urine are amongst the most common complaints. When a whole household is openly distressed by a child's refusal of food, by a failure to get the bowels open, or by a loss of control over the bladder, the child quickly catches the feeling of anxiety and distress and himself grows anxious and apprehensive about the matter. The mother of nearly all children with persistent anorexia or enuresis are unduly despondent and pessimistic, and when maternal confidence departs maternal competence goes with it. The complaint that the child never has and never will eat, or that the bed is always wet, is repeated again and again with such conviction that the child doubts it no more than the mother. The child never has and never will eat, or that the bed is always wet, is repeated again and again with such conviction that the child doubts it no more than the mother. The child never has and never will eat, or that the bed is always wet, is repeated again and again with such conviction that the child doubts it no more than the mother.

of 50 who died thirteen days after very extensive burns of the trunk and limbs there were multiple acute ulcers in the duodenum.

A possible etiological connexion between burns and ulcer of the stomach and duodenum has long been recognized. The association, however, is rare; Bolton suggests once in every 25 or 30 cases of burns. A perusal of the literature suggests that in former years the combination was more common than now, possibly because burns more frequently became septic.

Experimentally, the work of Rosenow in particular goes far to establish the importance of bacterial infection in the etiology of gastric ulcer. So long ago as 1857 it was shown by Lebert<sup>11</sup> that acute gastric ulcers could be produced, as part of a general pyaemia, by the intravenous injection of pus. Later Lettulo (1888),<sup>12</sup> Chantemesse and Vidal (1888),<sup>13</sup> Charrin and Ruffer (1889),<sup>14</sup> and others produced a similar result by the injection of a variety of bacterial cultures or their filtrates (staphylococci and streptococci, pneumococci, *Bacillus pyocyaneus*, dysentery and colon bacilli, etc.). The presence of bacteria has been frequently demonstrated in the margins and floors of both spontaneous and experimental ulcers, but the possibility of these being secondary invaders has always to be borne in mind.

In 1913 Rosenow<sup>15</sup> reported a series of experiments in which the intravenous injection of streptococci of sufficiently low virulence not to cause a general infection was followed in a certain number of cases by ulcer of the stomach and duodenum. The ulcers were usually single and deep, with marked tendency to haemorrhage and perforation, and in many respects resembled gastric ulcer in man. The streptococci were obtained from various sources, but especially from infected tonsils, and it was shown that the ulceration was the result of a localized infection, with secondary digestion.

Later, Rosenow and Sanford (1915)<sup>16</sup> showed the almost constant presence of streptococci, often in pure culture, in the depths of chronic gastric and duodenal ulcers in man. The organisms isolated were of a relatively low grade of virulence, but tended to localize in the mucous membrane of the stomach and duodenum, producing circumscribed areas of infection, with haemorrhage and ulceration, in a high percentage of the animals inoculated.

In subsequent papers Rosenow (1915,<sup>17</sup> 1916,<sup>18</sup> 1921<sup>19</sup>) showed the remarkable specificity of these and other streptococci, which tended, in general, to reproduce similar lesions to those from which they had originally been recovered. To this phenomenon he applied the term "elective localization." He also demonstrated that streptococci from cases of appendicitis, cholecystitis, endocarditis, tonsillitis, and dental apical infection were specially liable to localize in the stomach and duodenum, with production of haemorrhagic areas and ulcers.

In a recent paper Rosenow (1923)<sup>20</sup> goes on to show that as in man, so in animals, spontaneous ulcer of the stomach is associated with the presence therein of electively localizing streptococci, which reproduced gastric lesions—ulcer, haemorrhage, and infiltration—in no less than 86 per cent. of the rabbits and dogs injected.

## 2. The Action of the Gastric Juice.

The strict limitation of peptic ulcer to the stomach, first part of the duodenum, jejunum (following gastro-jejunostomy), and, rarely, the lower part of the oesophagus, at once suggests that the gastric juice plays an important part in the etiology of this disease. Normally the living gastric mucosa possesses complete immunity to the digestive action of the gastric juice, but immediately a portion of it becomes devitalized, whatever the cause, then the dead or damaged part becomes acted upon by the gastric secretion, and is gradually removed by peptic digestion, an acute ulcer resulting.

The pathology of the process has been studied and the importance of the gastric juice clearly demonstrated by Bolton. By the intraperitoneal injection of a non-lethal dose of gastrototoxic serum—that is, the serum of an animal, of different species, which has been immunized against the gastric mucosal cells of the first—he was able to produce within twenty-four hours or less patchy necrosis of

the stomach wall. After about forty-eight hours this necrosed tissue disappeared, leaving sharply punched out ulcers with clean bases, exactly comparable in distribution and appearance to the acute gastric ulcers of infective origin in man. If, however, the gastric juice was put out of action while the poison was acting, by the introduction into the stomach of a solution, over 1 per cent., of sodium bicarbonate no lesion of the stomach developed, even microscopical examination failing to reveal any pathological changes. Bolton has also shown, by experiment, that acute ulcer is much more easily produced in the digesting than in the resting stomach, and that in the former it is much more extensive in character. Moreover, ulceration produced in the presence of hyperacid stomach contents is much more extensive than that produced in a stomach whose contents are of normal acidity.

Recent experimental work by Mann, Kawamura, and Williamson (1922,<sup>21</sup> 1923<sup>22</sup>) has an important bearing on the relationship between acid stomach contents and the development of duodenal ulcer. By diverting the secretions which normally neutralize the gastric juice as it leaves the stomach to another portion of the intestine remote from the point of emergence of the acid, they were able to produce in dogs in a high percentage of cases typical sub-acute or chronic peptic ulcers in the intestinal (duodenal or jejunal) mucosa. These were quite comparable pathologically to the ulcers found in man.

It is obvious from these findings that while hyperchlorhydria, in man, will render conditions more favourable for the development of gastric or duodenal ulcer, yet it is by no means a necessary or essential factor. Gastric juice which possesses only the normal content of hydrochloric acid is quite able to play its part in the pathological process, although, as already shown, hyperacid juice has a much more powerful effect.

Examination of the stomach contents by the fractional method of Rehfuess shows that while hyperchlorhydria or a high normal figure is very commonly met with in cases of duodenal ulcer in man, it occurs in less than half the cases of gastric ulcer. Thus Moynihan (1923)<sup>23</sup> found that 73 per cent. of his cases of duodenal ulcer had a high hydrochloric acid content and only 21 per cent. of gastric ulcer cases. Bell's figures (1922),<sup>24</sup> at Guy's Hospital and Now Lodge Clinic, are appreciably higher, especially in the case of gastric ulcer—79.4 and 45.8 per cent. respectively. About one-third of all cases of gastric ulcer are hyperchlorhydric or achlorhydric, and about 10 to 12 per cent. of duodenal ulcer cases. It is perhaps worthy of note in this connexion that out of 150 cases of carcinoma of the stomach occurring in the present series of 6,800 autopsies, only 2 showed any evidence of simple ulceration at a distance from the growth, while in a series of nearly 40 cases of pernicious anaemia—one of the few diseases in which achlorhydria is constant—peptic ulcer, whether gastric or duodenal, was not once met with.

The importance of what he terms the "hypersthenic gastric diathesis" in the etiology of duodenal ulcer is strongly emphasized by Hurst (1922).<sup>6</sup> He points out that a certain proportion of healthy persons are hyperchlorhydric (10 per cent. of the healthy medical students examined by Bennett and Ryle, 1921<sup>25</sup>), and that some of them at any rate have also hypertonic stomachs. Such individuals, more often men than women, have an inborn variation from the average normal which manifests itself in hypertonus of the stomach with active peristalsis and rapid evacuation, and hyperchlorhydria with hypersecretion. In such people the "duodenal cap," by far the commonest site for chronic duodenal ulcer, is exposed, for several hours of each day, to an undiluted gastric juice of unusual acidity, and it only requires the intervention of one of the other factors already mentioned (especially bacterial localization) for a duodenal ulcer to develop. Hurst goes further than this: he believes that a duodenal ulcer cannot develop in anybody who has not this "duodenal diathesis."

Excessive smoking, which stimulates both the secretory and the motor functions of the stomach, is regarded by both Moynihan and Hurst as an important contributory cause of ulcer.

## B. ETIOLOGY OF CHRONIC ULCER.

The opinion has already been expressed that a chronic ulcer is merely an acute ulcer which has lasted a certain length of time. What, then, are the factors which prevent an acute ulcer from healing? In most of the experimental work which has been done on this subject the acute ulcers have healed with great readiness and in quite a short time (two or three weeks), and the difficulty has been, not to get them to heal, but to devise means to prevent them from healing—that is, to convert them into chronic ulcers, comparable to those met with in man.

The effect of diet has been studied experimentally by Bolton. He found that in cats a meat diet appreciably delayed the healing of acute gastrototoxic ulcers as compared with a control series of milk-fed animals. He attributes this to two factors: (a) the prolonged retention of meat food in the stomach, and (b) the more copious secretion of gastric juice induced by a meat diet.

In his next experiments Bolton first produced mechanical constriction of the duodenum in cats, and followed this up with the production of acute gastrototoxic ulcers, as before. In 10 out of 16 cats which survived these procedures, the effect was to cause a definite delay in the healing of the ulcers, which might amount to thrice the time taken for normal healing to occur. In no case, however, did a chronic ulcer result; healing was merely retarded to this quite moderate extent. Both Rosenow, and Mann and Williamson, on the other hand, have definitely succeeded in producing chronic ulcer by the methods already described, the one by streptococcal inoculations, the others by stopping the normal neutralization of the gastric contents by the pancreatic and other duodenal secretions.

Does the experimentally demonstrated relationship between delayed emptying of the stomach and delayed healing of acute gastric ulcer apply also in man? There is a certain amount of evidence that it does. Ulcers of the pyloric portion of the stomach are very liable to be associated with some degree of reflex pyloric spasm, with resulting undue retention of acid contents. Bolton and Goodhart (1922)<sup>26</sup> have further shown that pylorospasm tends to interfere with the regurgitation of alkaline duodenal contents into the stomach, and so to delay the process of intragastric neutralization, which according to Boldeyreff (1915)<sup>27</sup> is the normal method of control of hyperacidity. Both pyloric spasm and the hyperacidity which often accompanies it tend to induce hypermotility, while the ulcer itself is frequently associated with a localized abiding spasm in its immediate neighbourhood. It is reasonable to suppose that these factors exert an unfavourable influence on the ulcer.

The clinical effects of diet in promoting or retarding the healing of gastric ulcer are generally admitted, although opinions vary as to the degree of importance to be attached to this factor. The disturbances of gastric function, motor and secretory, which follow dietetic faults are of a kind which must undoubtedly interfere with the healing of a gastric ulcer whether or no they play any part in the initiation of the lesion. The mechanical effects of badly masticated food and the chemical effects of proteoplasmic poisons like vinegar (Bolton) may be mentioned in this connexion.

The distribution of chronic gastric ulcers as compared with acute would seem to have some bearing on the question. Acute ulcers are widespread in distribution, although most common in the pyloric half, and they are very frequently multiple; chronic ulcers are almost invariably single, and the great majority (90 per cent. of the present series) occur along the course of the original gastric tube—that is, on or near the lesser curvature. This would seem to suggest that the factors which lead to chronicity differ in some way from those which produce acute ulcer in the first instance. The comparative fixity of the lesser curvature, and the greater degree of trauma and friction from stomach contents to which the "Magenstrasse" is subjected may possibly explain, at least in part, why acute ulcers in this situation are more liable to become chronic than those in other parts of the organ. Radasch's (1923)<sup>28</sup> recent study of the distribution of the oxyntic cells of the

stomach fails to show any relationship to the distribution of either acute or chronic gastric ulcers.

In the case of the duodenum, the lodgement of highly acid juice for considerable periods of the day in the "duodenal cap" is probably an important factor in the conversion of acute into chronic ulcers. This would account for the preponderating localization of chronic ulcer in the first part of the duodenum in spite of the fact that acute duodenal ulcers are much more widely distributed.

## The Bradshaw Lecture

OR

## ANGINA PECTORIS: SOME POINTS IN PROGNOSIS.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS OF LONDON

BY

JOHN HAY, D.L., M.D., F.R.C.P.,  
HONORARY PHYSICIAN, LIVERPOOL ROYAL INFIRMARY.

Prognosis is one of the more fascinating aspects of medicine. It is a balancing of the probabilities and demands wide experience, intimate knowledge, and a keen sense of proportion combined with an instinctive capacity for weighing imponderables. Familial tendencies, the past history of the patient, the objective signs of actual disease, and those subtle but significant subjective discomforts pointing to depreciation of function must all be passed in review and their relative importance weighed before venturing on a verdict.

There are few conditions in which a clear statement as to the future is more anxiously demanded than where pain of an angular nature has manifested itself. For the victim is conscious that in him "the unseen seat of life, and the target of death" is mortally attacked. There is with each attack an ominous trembling of the very foundations of a man's being, which leaves behind it a shaken and apprehensive soul.

The problem of assessing the expectation of life under these conditions is most difficult, and even after careful consideration of all the facts and an attempt to view the symptoms in their correct perspective, an accurate opinion is not easily attained, and where so much is uncertain we must seek for any solid ground on which to base our opinion.

I have recently reviewed the records of 309 patients in whom the dominant feature was pain of an angular type, in an attempt to formulate the results of my personal experience, and have dealt with them more particularly in relation to prognosis.

## CAUSE OF ANGINAL PAIN.

It is not my intention to enter either the debatable ground of the essential nature of angina or of the special pathological changes which are said by some to be causally inevitable. We are now dealing not so much with the interpretation of the pain in angina as with the mortality.

It will be generally conceded that angular pain is the resultant of two factors: (1) afferent stimuli passing from the heart and aorta, and (2) the sensitiveness of the receiving apparatus—in other words, of those levels of the central nervous system associated with the heart and aorta; and it is to Sir James Mackenzie that we are more particularly indebted for the full appreciation of the importance of this latter factor.

From the interaction of these two we have pain, and the accuracy of prognosis will depend on a careful consideration of both, and a decision as to which of the two is dominant. The more exalted the sensitiveness of the segments involved, the more susceptible to stimulation, then the less ominous the outlook and the greater the ground for hope of a satisfactory response to treatment. On the other hand, the second essential matter for investigation is the reserve power of the heart, the health of the aorta, arteries, and myocardium, and also the permanent load on the heart of

Of another child it was complained that when he lost his temper he rushed into his mother's room and hurled the crucifix to the ground. I do not for a moment believe that such an act meant more than that he dreamed that in this way he could make the biggest sensation so far as this particular mother, a woman of strong religious feelings, was concerned. If it is instructive to note that in the society of the servants his proceedings were different. He had discovered, I suppose accidentally, in his struggles with his nurse, that a sensation could always be produced if he pulled her hair by the high braid enough. The screams and the expletions and laughter of the servants made him feel thoroughly important, and it was this device which he exploited when in their company. His antipathy to religion with them was no longer evident.

It might seem reasonable to conclude that acts of impiety and acts of indecency in a boy of 6 years of age implied a highly abnormal state of mind, and were the expression of deep-seated and complex emotions and impulses. I have little doubt of the conclusions to which an analyst of that school would be irresistibly driven. I believe that in reality they meant no more than that the management of an egocentric child, determined to assert himself, was somewhat at fault.

In the symptom which I have particularly chosen for analysis, that of the common refusal of food, it is easy also to discern the part which this instinct of self-assertion plays.

A little boy was brought to me in a motor car. He was a striking example of this anorexia nervosa. He had not seen the car since a visit paid to his grandfather three weeks before, when at the midday meal his refusal to eat had created consternation. Clearly the recollection of the way he had lived pleasantly in his memory, for when the car came to the door to bring him to me, thinking he was on his way back to his grandfather's, he said at once, "Not eat my dinner," a sentence which at the time had no meaning for his parents, but to which my explanation afforded the clue.

To understand the child, one must first understand the parent. The all-powerful influence proceeding from the parent must be utilized to strengthen, not to weaken, the

Dr. HENRY BOYLE (Hove) said that, with regard to the maintenance of the nervous child, it was due to inherent congenital factors, and possibly in quality, to that shown by Dr. Bolton in the brains of mental defectives? Or was it due to some defective development owing to faulty glands as Sir Frederick Mott believed was the case in dementia praecox? Or was it the stance of the disheathered child due to psychological causes? Might it be a mixture of one or more of these? It was the typical attitude of the fashionable woman of the post-war period, probably indicating truly the disheartened tired state of the women's minds, and thus being a fashionable presentation of the mood of the moment. Could this have been imitated by the children? In the last 40 children admitted to the Lady Chichester Hospital, Hove was bad, in 4 fair, in 16 good. In looking through the notes it struck Dr. Boyle that in those in which the stance was in good they were cases who were letting off emotional steam in some way, making some sort of adaptation of life, and not so dominated by fear as the others. One talked almost incessantly, another stole, was cruel, very polite, destructive, and so on. Again, did this stance necessarily indicate more anxiety than the normal attitude? Surely in both the child tried to get its centre of gravity over its feet. This could be done either as in the normal, by throwing the head up and back, the chest forward, and the abdomen back; or, as in the stance of the nervous child shown by Dr. Cameron, by hanging the head forward, the chest back, and the abdomen forward. Might this not have been difficult to throw the head to hide the face? It was difficult to throw the chest out and hang the head too. Another point was that this faulty attitude tended to get mixed in some cases more quickly than would seem likely unless Cameron, for self-assertion or for conquest of its surroundings was in many ways a valuable quality, but might lead to unpleasant results. Dr. Cameron felt that the handling of the child should be done as far as possible by the mother, and that she often needed help. The Parents' National Educational Union would be one way of reaching a certain

their deprivation produces a definite syndrome suggestive of deficiency disease. Such glands are nine in number.

Gland.	Chief Effects produced by Destruction or Deficiency of Gland.
1. The thyroid ...	Cretinism or myxoedema.
2. The parathyroids ...	Tetany, and derangement of calcium metabolism.
3. The islet tissue of the pancreas	Inability of tissues to utilize carbohydrates; hyperglycaemia and glycosuria.
4. The testicles ...	Eunuchism.
5. The ovaries ...	Premature menopause.
6. The suprarenal cortex ...	Asthenia, low blood pressure, and death in a few days.
7. The suprarenal medulla	The effects produced are doubtful.
8. The anterior lobe of the pituitary	Infantilism and obesity.
9. Posterior lobe of the pituitary	Increased carbohydrate tolerance. Diabetes insipidus (?).

Unfortunately only a few of these glands fulfil the second condition in at all a satisfactory manner. The evidence regarding the different glands is shortly as follows.

#### *The Thyroid.*

The evidence for substitution therapy in the case of the thyroid is practically complete. Administration of dried thyroid relieves the symptoms of thyroid deficiency, the active principle thyroxin has a known chemical formula and structure, and the activity of thyroid preparations can be estimated by physiological tests. Finally, it is known that thyroid extract produces its specific action when given by the mouth. In addition, hypertrophy of the thyroid produces a definite syndrome, and many of the signs of this syndrome can be produced by administering excess of thyroid gland.

#### *The Parathyroids.*

Unfortunately there is doubt whether the tetany produced by extirpation of the parathyroids can be relieved by administration of parathyroid. Biedl, for example, obtained consistently negative results in such experiments performed on cats.

The parathyroids are believed to have a double action—a detoxicating action consisting in the destruction of guanidino compounds, and a second action on calcium metabolism.

Vines<sup>4</sup> has reported valuable results from the administration of dried parathyroid in chronic sepsis. The preparation caused a rise in the calcium in the blood and a rapid clinical improvement. This action, however, is not of necessity an example of substitution therapy.

#### *The Islet Tissue of the Pancreas.*

As has already been mentioned, the connexion between the pancreas and carbohydrate metabolism has been known for more than thirty years, but the difficulty of extracting the active principle from the pancreas has only recently been overcome by the work of Banting and Macleod. Apparently the internal secretion of the pancreas can be temporarily replaced by the injection of insulin, and the use of insulin is a true case of substitution therapy.

It is instructive, however, to compare the difficulties attending the isolation and administration of insulin with the administration of thyroid. Dried thyroid given by the mouth is an effective means of substitution therapy in the one case, but in the case of insulin the discovery of a method for the extraction of the active principle was a matter of great difficulty, and even now when a suitable method has been discovered it is necessary to test every batch manufactured, since any small error in extraction will result in an inactive product; moreover, insulin has to be given hypodermically, for it is inactive when given by the mouth or when sprayed into the nose.

#### *The Gonads.*

The effects of castration or spaying have been known for centuries, and there is satisfactory evidence that many of these effects can be relieved by grafting of glands. The evidence as to the effect of testicular and ovarian extracts is, however, extremely unsatisfactory. Every imaginable claim has been made as to the action of these extracts, but all the more careful observers are very reserved in their opinions. Professor Murray<sup>5</sup> recently stated:

"There is very little satisfactory evidence that either testicular or ovarian preparations have any therapeutic action when injected

or taken by the mouth. The development of eunuchism after removal of the testicles and the corresponding condition after removal of the ovaries are generally considered to be due to loss of internal secretion of the gonads. There is, however, no evidence that either eunuchism can be removed by the use of testicular extract or the signs of a premature post-operative menopause averted by taking ovarian tablets. The relief of subjective sensations has been reported, but this is not sufficient evidence."

The use of testicular extract was, of course, the first example of attempted substitution therapy, for it was introduced by Brown-Séquard in 1889. There is, however, to-day no satisfactory evidence that we have yet succeeded in obtaining a preparation from either the testicles or the ovaries which will produce a true substitution effect.

#### *The Suprarenal Cortex and Medulla.*

These conjoined glands present a remarkable and even paradoxical contrast as regards endocrine therapy.

We know that the suprarenal cortex is absolutely essential to life and that its destruction rapidly causes death. Nevertheless, we do not know for certain whether the cortex acts as an organ of internal secretion, or whether it has only a detoxicating action, and no one has obtained from it an active extract.

On the other hand, the suprarenal medulla contains the intensely active substance adrenaline. The chemistry and pharmacology of adrenaline have been fully worked out, and it is possible to make fairly accurate quantitative estimations of the adrenaline content of the medulla. We know, however, very little indeed as to the physiological action of adrenaline. Recent work makes it doubtful if the destruction of the suprarenal medulla produces any very definite effects, and Cannon,<sup>6</sup> in a recent paper, concluded:

"There is no satisfactory evidence that, in natural quiet existence, the suprarenal medulla gives off any secretion whatever. In times of stress it is brought into action by nerve impulses, and may then support the influence of the sympathetic system and have besides special functions of its own."

The evidence for successful substitution therapy in the case of either the suprarenal cortex or medulla is therefore very scanty. In Addison's disease there is destruction of both the cortex and medulla, but extracts of the suprarenals do not cure this condition, although adrenaline may produce some temporary benefit.

#### *The Anterior and Posterior Lobes of the Pituitary.*

Deficiency of the anterior lobe of the pituitary is believed to produce Fröhlich's syndrome—namely, infantilism associated with obesity and torpidity. Cushing<sup>7</sup> found that large doses of the dried lobe by the mouth produced benefit in this condition; in one case 1.2 gram daily was required and in another extreme case 20 grams daily were needed. Nothing is known, however, about the chemical properties of the active principle of the anterior lobe.

The posterior lobe contains several active principles of unknown chemical nature, but with very powerful pharmacological actions. The extract is of value in obstetrics as an oxytocic, as a vaso-constrictor in shock, and as a gut stimulant in prevention of tympanites; finally, it produces a temporary curative effect in diabetes insipidus. This last example appears at first sight to be a clear case of substitution therapy, since diabetes insipidus is frequently associated with injury in the pituitary region and with pituitary tumours. Recent work has, however, shown that diabetes insipidus and other symptoms attributed to the destruction of the pituitary by operation, injury, or tumour are probably due to interference with the adjacent portions of the brain.

Pituitary deficiency also produces increased carbohydrate tolerance, and Cushing found that this was abolished by administration of posterior lobe extract. The extract produced its action on hypodermic or oral administration, the relative activities being as one is to four. This is remarkable, for, as regards its other actions, the posterior lobe extract has little or no action if given by the mouth, although it will act if sprayed into the nose.

The above summary shows that only in a few cases is there a satisfactory experimental basis for the practice of substitution therapy. The evidence in the case of dried thyroid and of insulin is practically complete, and the deficiency

Dr. W. A. PORRS (Birmingham) said that it was necessary to make a thorough physical examination, including an investigation of the endocrine glands, although treatment by endocrine substance was only occasionally effective. Still in some of the cases of pallor, albuminuria, enuresis, and digestive crises small doses of thyroid might act like a charm. Usually the nervous excitable child suggested a hyperthyroid function, but that hyperthyroidism might be a defence reaction, which was a sign of weakness. With tremors, parathyroid might be useful, while for the overgrown pituitary, extract might be necessary, owing to previous overstimulation of that gland. On the psychological side the attitude of the parents to life was as important as their attitude to the child itself. Passionate parents might terrify the child even if their temper was not directed against him. Their lack of control was a bad example, and example rather than precept was the most important factor for psychological adjustment. So also the drinking parent scared the child and set him an example of not facing the problems of life. Bad adjustment between husband and wife produced tension in the child, and confirmed his impression that adult life was simply not worth living, so that he remained a "Mary Rose" or a "Peter Pan." In treatment hygiene came first. Fresh air was the best nerve tonic. Too many clothes were debilitating and demoralizing. Frequent feeding upset the digestion, and also had a bad psychological effect. The child must not be unnecessarily interfered with, but left to play naturally and to work out his own salvation. His life must be simple and hardy, not sensational. He must be trained to go into the dark without fear, though anything frightening must not be forced. For this there should not be a night-light, but a little light kindled in his mind. To diminish morbid fear and for many other reasons every child must receive simple teaching in religion and the origin of life from his mother. Teaching in both must be of the simplest kind, as his questions showed he was fit to receive it. If he was not taught that there was an almighty beneficent Power which would help him, the imagination every child had would fill the darkness with bogies and powers of evil. So also, if not taught in the right way at the right time about the origin of life, a bad companion might suddenly flood his mind with false teaching, terrifying in itself and possibly leading to bad habits. The possibility of such habits as cause or effect of nervousness must not be overlooked.

Dr. H. CRICHTON MILLER (London) said that Dr. Cameron had given a very vivid picture of the nervous child. On the physical side they all recognized, no doubt, the identity of a type that was only too familiar to them all. He regretted that Dr. Cameron did not venture on some theory of etiology, however speculative. For his own part, Dr. Crichton Miller wished that so careful an observer as Dr. Cameron would undertake a series of tests in children of this group to demonstrate the normality or otherwise of their calcium metabolism. He suspected that they inclined to look too exclusively to skeletal maldevelopment for evidence of faulty calcium metabolism. The nervous child, as described by Dr. Cameron, might conceivably owe to this cause not only its amyotonia, but also other features of the syndrome. Were that to be substantiated recent observations, if confirmed, might lead them a step further on to a possible failure of parathyroid function as the essential etiological factor.

The nervous child, as Dr. Cameron described him, and as they accepted him, was by no means the only type to be found in the much wider class that the Americans described as the "problem child." Dr. Cameron had very rightly chosen the greatest factor in emotional maldevelopment—faults of parental control—to discuss alongside the wide, if vague, group of physical maldevelopments that made the nervous child. Let them by all means establish correlations between the physical and emotional whosoever they could. Nevertheless, they must not mislead themselves. Failures of adjustment, functional neuroses, and defects of conduct could and did show themselves with notable frequency among children who did not conform in the least to Dr. Cameron's description of the nervous or amyotonic child. The "maternal traction"—as Dr. Cameron aptly called it—

was often exercised so powerfully as to ensure failure of emotional development in children who were physically robust and in no way predisposed on the somatic side to failure on the psychological side.

It all came to be a question of the balance of opposing forces—the forces that made for growth and progression, and those that made for stagnation or regression. Among the forces that made for progress they had the inherent tendency of any growing thing to realize its destiny, to fulfil its function, and to attain to maturity; they had also all those emotional forces of the environment which lured the child on to growth, and which might be roughly classed under the heading of progressive idealism. On the side of progression also was the stimulus of social opinion, especially that of other children. On the other side they had the counteracting forces that made for regression—all those failures of vitality which neutralized the biological urge of growth, the menace of maturity, and the too alluring call of the cradle, or, as Dr. Cameron would say, the irresistible "maternal traction." There were some nervous children who, in spite of an excellent environment, failed to develop because, being of the amyotonic type, they never had sufficient vitality to achieve; their biological urge was a negative quantity, and the line of least resistance was their constant choice. They had to bring up their children in such a way that they should not feel that adult solicitude was to be secured by infantile helplessness, nor yet by exhibitionism and delinquency. Dr. Crichton Miller differed from Dr. Cameron when he said that "all the interest and remark are to be aroused by success." The really curative atmosphere was that in which normality was taken for granted; and the reaction of the adult to abnormality should always be to withdraw the limelight.

There was no symptom with more interesting psychological ramifications than that of enuresis nocturna. It was a condition in which archaic traditionalism still seemed to dominate their therapy. The unfortunate victims of belladonna poisoning, bougie treatment, and electro-therapeutics, were always the most difficult to cure—and little wonder. It was probable that the physical basis of this condition was thyro-pituitary deficiency. Be that as it might, the fact remained that no condition was more associated with suggestive factors. Most of the patients auto-suggested themselves into a chronic state of fear and shame, while the adult forces of hetero-suggestion were exemplified by the waterproof sheets, the 10 p.m. waking, and even the nightly prayer for deliverance! They must remember also that the symptom of nocturnal enuresis was the most complete symbol of infantility; it therefore served as the best defence against the dreaded implications of growth. He remembered a boy of 10½ who had been a life-long victim of this failing. He was an only child, and his mother was a widow. It was pointed out that his condition was becoming serious, because the child could not go to a boarding school till he had overcome it. It did not require a very elaborate investigation to reveal the fact that the symptom was serving as a defence against separation—not only for the sufferer, but for the mother. In point of fact, they both preferred this disability to the pain of separation, which was becoming imminent. They must also remember that to certain children this symptom gratified a feeling of importance, and a thirst for power, in that it was very obvious how much disturbance and trouble was caused. Then there were cases in which children had been told that unless they overcame their failing by a stronger effort of will they would find themselves ostracized from society and pariahs in the world. An instance of this was a boy aged 11 who was brought to Dr. Miller with a long list of misdemeanours, including meaningless thefts and unnecessary lies. He was as healthy as one could wish. All his life he had been a victim of nocturnal enuresis. His mother described one of his most incompressible delinquencies, which consisted in travelling from school to a station beyond his home, and then evading the ticket collector, and walking back. The fact was that the child was suffering from a profound sense of adult injustice. He believed that his enuresis was beyond control, and that therefore the threatened penalties of society were undeserved. The revenge motive stimulated him to "get his own back" from society by any means at his command,

It will now be found, on pulling gently on the tip of the nose, that the shape of the organ can be exactly reproduced, at which stage one realizes that the undercutting process has been sufficient.

It now remains to skin-graft the raw surface produced on the under surface of the skin of the nose, and for this purpose pressure must be applied by the method of Esser modified by various surgeons at Sidcup, and applied by me to this particular purpose.

Dental modelling composition is sterilized by boiling, and a sufficient quantity in a pliable state pushed in through the mouth opening into the cavity made by the undercutting process; but, before this—to prevent the moulding material passing to the post-nasal space—plugging should be inserted into the nose, and left flush with the pyriform opening. The moulding material inserted may now be pressed up from the outside with the fingers, so as to reproduce the shape of the nose, but in order to allow for a certain amount of contraction of the skin-graft it is better to overdistend the raw area at this stage.

While the moulding material is still warm the upright with expanded end, also heated, can be pressed into the mould and fixed by a screw to the dental splint. While the surgeon is manipulating the mould into a convenient shape the assistant pours cold water over the surface of the skin, or sprays cold water up the nostrils or through the mouth opening.

The mould now sets hard, and can be withdrawn together with the upright portion of the splint. Sometimes difficulty is experienced in removing the mould, either because the opening from the mouth into the nose is not big enough, or because some of the moulding material has been expressed out of the nose into the anterior nares and sets there; this causes a sort of hook and prevents the removal of the mould. These little complications can be avoided during the setting of the mould by cutting off the excess portions with a hot spatula.

Examination of the mould will now enable the surgeon to see which portions of it have been in contact with the raw surface produced by the undercutting. They are usually confined to the whole of the front surface of the mould and the lateral portions of the back. It is this area that requires skin-grafting. The plugging inserted to prevent the mould being pressed to the back of the nose is now removed.

The removal of a large graft is the next essential. If the patient is a male, an area free from hair is chosen on the inner side of the thigh.

It is of enormous importance, both for the success of the graft and for the ease of application, that the skin graft should be cut sufficiently large to cover the whole area in one piece. There seems to be no royal road to the successful cutting of big grafts, the personal factor of the surgeon, and the patient's skin, and assistance, all being important, and perhaps the most important.

The graft is now taken and stretched firmly over the whole surface of the mould corresponding to the raw area so that there are no wrinkles or slackness in the graft, the raw surface of the skin graft being, of course, outermost.

When the graft is a big and good one, the grafted thumb is the most useful spreader. When the graft is in shreds or smaller pieces, recourse should be had to non-rat-toothed dissecting forceps.

Fig. 9.

Fig. 9 shows the first stage of reconstruction—namely, removal of the lip of the nose from its normal position by division from the various dissection of the nose. Fig. 10 shows the appearance of the patient after rhinoplasty by tube pedicle from arm.

Care should be taken that the graft reaches well over the top to the back surface, so that when the graft and mould together are pushed into position there is no disturbance of the position of the graft on the mould. The wound is cleared of clot, and the mould with skin graft thereon is inserted.

It now remains to fix the upright of the splint and send the patient back to bed.

At the end of ten days the case is referred to the dental surgeon, who removes the mould gently and cleans up the cavity, when the whole of the raw surface of the nose will be found to be perfectly covered with skin. It is as big a certainty as there is in surgery.

Either the same mould cleaned up, or a fresh one made of black gutta-percha, is now inserted, and can be removed daily for another week or ten days by the doctor in charge of the case. At the end of this time the graft is quite firm, and the case can be handed to the dental surgeon to be fitted with a more permanent appliance. This is moulded by the dental surgeon so that the nose takes on a good shape, and the mould can be removed by the patient daily for cleaning.

In order that the mould should be removable there is naturally a displacement forwards of the upper lip, a deformity which must be endured until the final stage.

The patient is sent home for two months, when the second stage is performed, which consists in removing the implantation of a cartilaginous bridge between the outer skin of the nose and the inner skin graft. Sometimes the cartilage can be put in through the columella, and sometimes through the glabellar region.

The appliance is now discarded, and the lip allowed to fall back into a normal position. If a permanent oronasal communication remains, sufficient of the opposing surfaces may be rawed to ensure its closure. The two cases (Figs. 1 to 8)\* are published to illustrate the surprising results obtained by this method.

When there is destruction of the outside elements of the nose in addition to the above, the case develops into one of more or less extensive rhinoplasty.

The methods of rhinoplasty in specific cases differ little from those of any other destruction of the nose, save that in specific cases some small portion of the columella or portions of the bridge skin only may be destroyed. The scope of this paper does not admit description of the various methods of rhinoplasty.

The best result can usually be obtained by a combination of the method described under the second heading, coupled with the requisite grafting of the new columella or other portion: having carried out the two stages as described in Class 2, a columella was provided, and the final result was of a pleasing and satisfactory nature.

In another more extensive destruction of the bridge of the nose I was foolish enough to attempt to implant cartilage as a means of restoration, for although a satisfactory raising of the bridge occurred, the syphilitic character of the deformity remained, and the anterior nares still looked forwards instead of downwards. The

Fig. 1 to 5 were reproduced in Plastic Surgery of the Face (Oxford Medical Publications).

even though they involved considerable trouble to himself. Dr. Crichton Miller mentioned three different aspects of one problem of the nervous child in order to show how varied might be the underlying causes at work, and therefore how useless it was to expect results from routine treatment.

Sir ROBERT ARMSTRONG-JONES (London) was of opinion that the nervous child was a genus with several species, and this accounted for the varying physical symptoms presented—for instance, a limpness and consequent posture with amyotonia in some, whilst there was a definite tendency of karatonia and flexibilitas cerea in others. At any rate there was no doubt that these symptoms were the precursors to a later mental collapse unless taken definitely in hand and treated, and the indications for treatment must be based upon the "tripartite" aspect of man—namely, the bodily, mental, and spiritual or ethical. It was possible to cultivate the bodily only or mainly, and so obtain a physical Hercules but a mentally undeveloped person. It was possible to cultivate the mental and overlook the spiritual, so that one could see the moral monster. The aim of treatment must be based upon the three aspects. First, in regard to the bodily side, there must be adequate sleep. Rest was essential for these restless, unbalanced, easily fatigued, and excitable children. They should be in bed by 8 o'clock, and from 12 to 15 years of age must have twelve hours' sleep, and if not sleep they were resting whilst in bed on their back. These children were almost invariably light sleepers, and often experienced dreams and sudden starts or "screams." The room should be a quiet one and darkened. No lessons should be indulged in for an hour before bed. The primitive instincts were obvious in many of these nervous children. There was a fear of the dark, and the mother had an unusual power over the child towards dusk or the falling of darkness, and could do much to relieve and reassure the child and soothe its fears or correct its conduct. This was a very impressionable hour in child as well as in animal life, and rest and restoration could be greatly aided by a warm immersion bath before bedtime. As was well known, the skin was developed from the same parent embryonic layer as the brain, and every part of the skin was represented in the brain, so that light massage might greatly assist rest and sleep. The clothing must be light, and the clothing should be suspended from the shoulders and not the waist, the shoes should be comfortable, and no garters worn. All wet clothes should be changed at once. The food of the nervous child was important. Fruit was essential, and the juice of an orange was most restorative. The food should be at correctly regular intervals. The nervous system must be sustained at regular intervals, and there should be adequate fat and sugar; these could be well supplied in home-made toffees at meal times. The utmost attention should be given to the regularity of all the functions, and syrup of figs or fluid magnesia were good friends. Exercise should not be indulged in so as to produce fatigue. The hands should be encouraged by some mutual interest. The eye and hand went together as much as did hearing and speech. The hand was the companion to the eye. One of the chief senses connected with education was the muscular sense, and the muscular element of thought had hitherto been very inadequately worked out. The first development of attention was in muscular movements, and attention was the basis of the will, which must be strengthened in the nervous child. In a baby and in early life there was constant movement, and nothing was so characteristic of early infant life as its general undifferentiated muscular movements. As healthy growth proceeded some peculiar association of pleasure or pain was associated with some movement, and the mind was arrested, as it were, and a special impression was made on consciousness. This detention of the mind was the earliest growth of the will, for it tended to keep off or to inhibit some movements which were useless and random, and to fix the attention upon those that were useful; the recollection of this utility could be revived, so that purposeful movements occurred, and a deliberate adaptation and a desire resulted. The first act of will was attention, and when the attention of the child could be fixed it was the first stage

in successful education and treatment. The attention was no special faculty and it was no separate activity; it was a detention of the mind and a concentrated activity of the conscious stream. There was a maxim in the proper upbringing of children: "Don't say 'don't.'" The iteration of "don't" was to suggest the opposite. The will to do came before the will not to do. They should not coerce the nervous child, but express disapproval by reasoning to it, use patience, and show an example, which was the best appeal. Contrariness was the most marked symptom of the spoilt child, and was often an indication of fatigue in the nervous child. If he was troublesome, let him see where his naughtiness and contrariness led to. If he was late for breakfast let him be left. If he refused food, send it away. If he refused to dress let him stay in bed. He believed the nervous child was very quick at self-discrimination and self-analysis, and he soon learned the value and results of retributive justice. Good and unperturbable temper was necessary in dealing with the nervous child, who was quick to realize approbation. The child learned that he could obey and disobey, and his imitative tendency would help him to remember a good example as a suggestion. Lastly, he believed strongly in encouraging a child to do the "right," to learn there was a right and a wrong, to show him he had the choice, and that a responsibility lay upon him to do the right. The feeling that there was someone very great and very mighty on whom he could lean as on his parents was a great factor in children's minds, and that this great Person was pleased with right conduct and grieved at the opposite appealed as a most powerful incentive and motive to right conduct. He believed there was in human beings a moral sense just as effective and powerful as the sense of sight or the sense of hearing. The four periods of life were a maxim: (a) the period of infant life, during which the senses were providing information and links of association, but which was mainly a period of reflex actions; (b) the perceptive period of discrimination and differentiation; (c) the period of intellectual growth, in which the attention, imagination, and memory were cultivated; and (d) the period of reflection, when unselfishness appeared and the growth of the will was perfected through self-control and reason—a period when the social spirit and the regard for others was being fully developed and perfected, and treatment must be based upon a recognition of these.

Dr. R. G. GORDON (Bath) said that the individual characteristics of the child were important from the psychological point of view. It might be interesting to consider the predisposition of nervous children, and for purposes of discussion McDougall's treatment of this was useful, though his claim for elemental characteristics of his instinctive reactions could not be substantiated. He described certain instinctive dispositions, such as pugnacity, fear, curiosity, sex, and so on, which were built up and integrated together to form the personality and character in the normal individual; these instinctive dispositions varied in their relative proportions, but only within certain limits. In the nervous child these dispositions were out of proportion and lacked proper integration. McDougall had shown how several of these might be combined to form compound emotions and sentiments, but did not sufficiently recognize the new and unique quality which emerged. When mercury and chlorine combined under certain conditions a new entity—calomel—emerged, but under other conditions a different entity—corrosive sublimate—emerged. In the nervous child it was often found that instinctive dispositions combined and emerged as some characteristic of behaviour different from the normal. Failure of general integration was another important factor in the make-up of the nervous child. The question to be answered was why these failures took place. From the neurological standpoint they must look to some failure in cortical function, for it had long been recognized in the motor and sensory realms that the cortex was essential for the integration and control of lower functions. More lately Bianchi had shown that the frontal lobes had to do with the integration and control of emotional dispositions. In the case of the nervous child there might,

method originated during the war by the speaker is more applicable in this class of case, and the first step should be a division of the nose horizontally above the alar cartilages. An incision is carried right through into the nasal cavity, and, laterally, above each ala until the tip of the nose, alae, and columella resume a normal position (Fig. 8). A large fistula is then apparent in the middle of the nose, the margins of which, after trimming, are treated by sewing skin to mucous membrane to prevent retraction of the tip.

The case is left for two months, at the end of which time reconstruction proper is carried out. Skin flaps, suitably designed, are hinged across the gap with the skin surface towards the nasal cavity to complete the lining of the new nose.

A shaped flap is then taken from the forehead, or, as in this case, from the arm, to complete the nose. (Fig. 11.) Two weeks later the pedicle is divided. It remains at a laginous bridge (Fig. 10).

It is to be noted that there is undoubtedly a greater risk of gangrene occurring in a flap in a syphilitic case, which may be due to some change in the arterial walls. I sincerely hope that these few remarks will induce the plastic surgeon to attack these syphilitic cases of nasal deformity with more definite principles and more gratifying success. Unless an adequate provision be made for the loss of the mucous membrane in these cases the appearance of the patient, however improved by the operation, will continue to be that of a typical syphilitic, who will still be shunned by his fellows. The patient should be under control by specific remedies, but a positive Wassermann reaction is not a contraindication to reparative proceedings.

## ORGANOTHERAPY IN DISEASES OF THE EAR, NOSE, AND THROAT.

WILLIAM J. LEIGHTON, M.D., B.Ch., BRISTOL,  
Honorary Assistant Surgeon, St. John's Ear Hospital,  
Manchester.

If one were to be asked to state in general terms what subject was engaging the attention of the greatest number of medical men at the present time, I think that the truest answer would probably be "endocrinology."

The influence of the endocrine organs on the economy is so widespread, and their derangements are so common, that specialists in every branch of medicine are bound to consider the question of hormone dysfunction in relation to almost every morbid process, and to experiment freely with various glandular extracts to endeavour to determine whether any useful therapeutic effects are to be achieved by their exhibition. This applies not less to otolaryngology than to other branches, and I wish to present a few notes to this Section, in order if possible to arouse discussion and stimulate interest in the subject.

Some of us may, perhaps, be so interested in the surgical, operative, and manipulative side of our specialty that we tend to forget the claims of internal medication. While, naturally, a course of thyroid feeding would be useless, in a case of lateral sinus thrombosis, yet there are numerous conditions in which organotherapy forms a useful adjunct to surgery; some in which it may be tried with a fair hope of success; and possibly a few where it may throw light on otherwise obscure problems of pathology and treatment.

There are so many organs which supply an internal secretion necessary to health, the manifestations of their derangements are so complicated, and the interactions of the different glands, but I may perhaps be allowed to formulate certain general rules of endocrinology.

The endocrine organs may affect the organism unfavourably from (a) excessive secretion, (b) the deficiency of secretion, (c) perverted secretion.

2. Alterations in the quantity or quality of the secretion of one organ may produce alterations in one or both directions in that of one or more other organs.

3. If an organ is secreting less of its particular fluid than is required for the needs of the body, feeding the patient with that extract will not only supply the deficiency at the time, but, if the process is a functional one, or mild organic, it will give the diseased organ a rest, and enable it to take up its duties in full later on.

4. An endocrine organ may enlarge on account of a demand made for an increased supply of its secretion, possibly from a distant part of the body. Feeding it to the patient will relieve the strain on the gland and enable it to keep its normal size.

Bearing these principles in mind, let us consider under what conditions the use of glandular extracts may be found useful in the treatment of diseases of the ear, nose, and throat.

McCarrison<sup>1</sup> has shown that intestinal and other sepsis causes an increased demand for thyroid secretion. This leads to increased thyroid activity, acinar proliferation, and round-celled infiltration, resulting in a goitre. The round cells undergo their usual transformation into fibrous tissue, the glandular elements are strangled, and finally a condition of hypothyroidism results, with an enlarged thyroid. The action and results of the round cells in these cases is very similar to the process seen in scirrhus cancer. It is very interesting, in view of McCarrison's work, to notice how swollen thyroids associated with sepsis often diminish in size when the sepsis is cured.

Miss R. N. consulted me on January 25th, 1922. I need not detail her symptoms, etc., but the condition was one of post-influenzal emphysema of the arm, of Higgmore's. The thyroid gland was one of post-influenzal emphysema of the arm, of Higgmore's. The thyroid gland was one of post-influenzal emphysema of the arm, of Higgmore's. The thyroid gland was one of post-influenzal emphysema of the arm, of Higgmore's.

I have so often observed thyroid enlargement in cases of nasal and aural suppuration that I am now in the habit of prescribing small doses of thyroid extract from the first interview, as well for cosmetic reasons as to supply the increased secretion required by the body for the combating of the sepsis. Of this need the thyroid enlargement is a signal and proof. If the gland does enlarge the dose is increased.

McCarrison<sup>2</sup> points out the necessity for a careful search for septic tonsils or nasal sinuses in all cases of exophthalmic goitre. I may here remark that it is a difficult matter to get accurate measurements of the neck, and very easy to make a mistake. The best way is to take a definite point, before and after—that is, to place the tape over the retroauricular prominences behind and the most prominent part of the gland in front. At present I have a young lady under my care who was tracheotomized in infancy. The scar makes a most valuable landmark.

Occasionally we see cases which may be referred to the pituitary. The amount of information which has been collected about this organ in recent years is astonishing. When preparing this paper I had the curiosity to look up the Halliburton's *Physiology* which I used in my student days. It is dated 1900. All that is there stated about the physiology and pathology of the pituitary is comprised in the statement, "A disease of the pituitary body produces the condition known as acromegaly, in which the bones of the limbs and face hypertrophy." Compare this with the fifty pages—one-seventh of the whole—devoted to it in Mason's *Endocrine Glands* published last year. I shall not enter into the complicated functions and relationships of this important organ further than to say that the head-ache and eye symptoms associated with some of its derangements have to be diagnosed from ophthalmic sinus disease. The headache comes on in the morning, may persist or pass off during the day, is deep-seated behind the eyes, and is frequently associated with ocular symptoms, and has often a relationship with the menstrual function.

then, be something wrong with the frontal lobes. That there was nothing gross was obvious, because many of these children grew out of their troubles. It must be recognized that the adjustment at the level of the frontal lobes was very delicate, and almost anything might upset this. Cases might be quoted where this dysfunction of the frontal lobes was apparently induced by malnutrition and lack of vitamins, endocrine imbalance, infections (especially syphilis and encephalitis lethargica), and the influence of the environment. This last factor was by far the most important, and no treatment could be of any use unless the environment was considered. In treating a nervous child they must consider his make-up, and to do this they must use some analysis, but the elaborate technique of psycho-analysis had no place, for the child was quite incapable of grasping what the analyst was at.

Dr. C. F. HARFORD (London) said that Dr. Cameron had sketched the posture of the nervous child, and had shown that the crooked back was closely related to a warped mentality. He regarded courage, promptitude, and presence of mind as distinguishing features of the well trained recruit with his erect and alert bearing, a striking contrast to the timid child whose characteristics they were called upon to study. Dr. Harford proposed to advance another proposition, which was that the crooked eye was another mark of an unstable mentality. To illustrate his meaning he had selected a series of cases taken from one morning's experience during the present month in his consulting room in a provincial town which he visited once a week. In the ordinary course of his ophthalmic practice he was seeing cases referred to him by the school medical officer, when there walked in a mother with three children—a girl aged 13 and two boys aged 8 and 5—both of these latter having pronounced left internal strabismus. As it turned out, the girl also had left internal strabismus, which was not constant. The boys were instances of the two types of children already described to them, which, following Dr. Crichton Miller, Dr. Harford referred to as the suggestible and the rebel. The elder boy was essentially the rebel, always in trouble but absolutely unmoved by punishment, though caning seemed to be his almost daily portion. He had the dare-devil spirit, climbing into almost inaccessible places, running to horses' heads, and so forth. He was described as very nervous, and this was evident when Dr. Harford had to put some ointment into his eyes, a process which he resisted, although his brother and sister had been most amenable to treatment. The younger boy was the suggestible one, imitative to an extreme degree, so much that he had tried to cut off his hair in order to be like a master who was bald. He was, however, said to be obedient and helpful at home. The girl was fond of domestic pursuits—knitting, cooking, etc. Both boys were left-handed, particularly the elder. These children were members of a family of nine. The eldest brother, aged 22, in the Royal Marines, squinted as a child and was backward in speaking and was also left-handed, but he had grown out of all these habits. The mother squinted as a child, but otherwise there was nothing calling for comment upon her side of the family. The paternal family history was all-important. The paternal grandfather, who was deaf, was a most eccentric man. He married late in life, and lived to over 90 years of age. He had three daughters and two sons, but he would not support wife or family, the burden of which fell on his wife. The two sons were twins, one of them being the father of the family under review. He was the weaker twin, but he outlived his brother, who died at the age of 2. One of his sisters was left-handed, and another was so backward in talking that she did not speak until she was 6 years old. This family illustrated the point to which attention had been particularly drawn by Mr. Inman of Portsmouth,<sup>1,2</sup> as to the connexion of squint with left-handedness and stammering, with which they might link up all kinds of speech defect. On the same morning Dr. Harford saw a girl, aged 7, with right internal strabismus but without any significant family history. This child was in difficulties at school, for while she was brilliant in some subjects she

was backward in others. She was a very lively child, excitable and emotional, and very fond of minding babies. He suggested that in her case, as in that of the girl already mentioned, the maternal instinct was developing, and that the ordinary school routine conflicted with their special tastes and gifts. The next case was a girl who had a squinting brother. He should have come to see Dr. Harford, but he suffered from diarrhoea whenever excited, and had been upset by the bad thunderstorm. This boy was described by his mother as an imp, recklessly climbing trees, but, on the other hand, one who cried too easily. These were cases which could be multiplied almost indefinitely, especially by Inman, and Dr. Harford was absolutely convinced that the incidence of squint might be regarded as one of the valuable clues to deeper emotional disturbances in which parental complexes, particularly on the father's side, might be looked for. One other reminiscence from the same consulting room might be quoted of two boys, both squinters, whom he saw on the same morning, some weeks previously. One was a veritable acrobat, the other a boy of an irritable disposition who, like his father, had no idea of patience, especially if it meant waiting for a meal. Clearly there was some family jar in this case.

These notes may be taken as a fair sample of the evidence which had been obtained in cases of squint during the past eighteen months in which Dr. Harford had sought to follow out the line of investigation suggested by Inman. His observations had been made in the ophthalmic outpatient department of a large general hospital, at a school clinic in the East End of London, as well as in school work outside London and in private practice. In each case the results had confirmed Inman's view. His object in putting forward this evidence in the present discussion was not so much to speculate as to the origin of squint as to suggest that its occurrence might form a valuable aid in the recognition of emotional conflicts which might influence profoundly the child's future. He had in three previous papers<sup>3,4,5</sup> considered at some length the relation of ophthalmology to psychology and psychopathology, and expressed the view that when this connexion was more generally recognized a new field for research would open up, which might be of great benefit in the recognition and treatment of those elusive disorders which they were investigating at that meeting. In the case of squint, mainly owing to Inman's work, they could link together the ocular defect and the psychological syndrome which accompanied it. He did not dispute the importance of errors of refraction and the necessity of correcting them where they existed, but they had to think of the child in general, and not only of the troublesome defect which was but one item in the case. In the opening paper three elements in the behaviour of children were singled out for special notice. These were: (1) the child's proneness to the influence of suggestion; (2) his desire to oppose; and (3) his instinct to assert himself, to attract to himself, and to make himself the centre of the picture. Each of these elements might be found in the history of squinting children, combined with some parental difficulty. If one endeavoured to select one factor which was common to all these cases it was fear, and when they spoke of the nervous child they usually meant the frightened child. Thus, if they passed to the question of treatment, since they were dealing with a psychological condition they must deal with it by some method of psychotherapy. As he stated last year in this same Section,<sup>6</sup> he was of opinion that some measure of analysis and of suggestion was common to all systems of psychotherapy, and that the final result of successful treatment was auto-suggestion. He believed that a carefully devised system of collective teaching in auto-suggestion, in which the parent was also included, offered the best prospect of dealing with the shy, reserved, irritable, or distinctly frightened child, and he hoped that all who were interested in the subject might be able to co-operate in some way in securing the best results. Dr. Cameron had alluded to the fact that the subject was one which claimed the attention of parents and teachers as well as the medical profession. The risk was that the two former classes should

I recently saw Mrs. S., aged 38; she has three children, the youngest 3½ years old. She menstruates every four weeks, for four days; how somewhat scanty. She complains of deep-seated "boiling" or "burning" pain behind the eyes, especially on reading or sewing. "The headache formerly began the day before menstruation, and ceased when the flow started, but for some months now has been almost continuous. She suffers from bad dreams. She has not noticed any increase or diminution in the amount of urine. Her carbohydrate tolerance is fairly high, about 150 grams. She has been getting stout for twelve months. She is normal; no signs of intraocular pressure or pus. I referred her to Dr. Walter Sykes of Preston, for an opinion on her eyes. His report was: "The eyes are emmetropic, she gets full vision under homotroping. The fields are slightly contracted in both eyes, and the veins on the discs are very engorged." I put her on pituitrin who had vanished. She is now able to read with comfort, and only takes the tablets for a week before menstruation begins.

I do not know whether cases of this type can in any way be correlated with those referred to by Sir St. Clair Thomson in the British Medical Journal of June 2nd of this year, where the sphenoidal sinuses have been opened for retrobulbar neuritis, and found to be healthy; but I think that this case opens up an interesting field for inquiry. Mrs. S. was certainly suffering from pressure on the optic tracts, and this pressure has been relieved, in my opinion, by taking the strain off the overworking pituitary. I quite admit that the time (three months) is too short to make any definite pronouncement, but I shall watch her future with interest.

In cases where we find a diminished power of conduction of the eighth nerve, it is not sufficient to label the case "labyrinthine deafness," order strychnine and massage, and pass it on to the group of uninteresting incurables. More particularly does this apply to the period of late middle life, on its merits and a more definite diagnosis arrived at before sentility has set in. Each case should be examined among the more important causes are:

- Haemorrhage into the labyrinth.
- Syphilis.
- Leukemia.
- Locomotor ataxia.
- Concussion.
- New growths affecting the labyrinth, eighth nerve, or brain.
- Suppurative labyrinthitis.
- With these I do not propose to deal.
- Diabetes.
- High blood pressure.
- Low blood pressure (asthenia).
- Otitic deafness.
- Neuroses, including hysteria, neurasthenia, and psychasthenia.
- Hypothyroidism.

Many of the latter group are amenable to organotherapy. Since the researches of the Toronto school hormone therapy in the form of insulin injections has definitely come into being. I need not enlarge upon this subject, as we would probably refer such cases to an appropriate physician; but it is well to bear in mind that deafness may be the first symptom of an otherwise unsuspected glycosuria. I have seen several such, and thereby received a useful reminder that it is always necessary to examine the urine in cases of labyrinthine deafness.

### Abnormal Blood Pressure.

I find that the sphygmomanometer is one of the most invaluable instruments in my armamentarium. No case of nerve deafness should be allowed to leave the consulting room without having the blood pressure estimated. Cases of high blood pressure due to renal or cardio-vascular trouble we also generally refer to the physician, but there is a large group of cases termed by Sir Clifford Allbutt "hypertic," in which the high pressure does not depend on heart or kidney disease, which the aurist may wish to treat. These people are often afflicted with nerve deafness, and that bugbear of the otologist, tinnitus. Here again the deafness may be the only symptom which the patient has noticed. It does not add to one's reputation if such a case is missed, and subsequently the cause is detected by a more wide-awake colleague.

I am not going to be so foolish as to tell an audience like this that I know of a universal panacea for tinnitus, but I do state that many cases can be relieved, if due to high blood pressure, by appropriate treatment, including the exhibition of certain glandular extracts. Picture to your-

### Asthenical, Hysterical, and Neurasthenical Affections of the Ear, Larynx, and Pharynx.

These may be considered together. I need not dilate upon the symptomatology, which is perfectly well known to every member of the Section. During the past few years the number of cases of eighth nerve paresis due to influenza has been very great. Many observers consider that the post-influenza asthenia is mainly due to adrenal exhaustion. Acting on this idea I have found great benefit is to be gained from giving adrenal gland in such cases. The whole gland appears to be more effective than adrenaline, which is the extract or active principle of the medullary portion. This may be explained on the hypothesis that adrenaline is actually formed in the cortex, and stored in the medulla. It is quite possible that other substances of the adrenal gland bear a part in the etiology of the various neuroses which are as yet imperfectly differentiated, but which are included under the headings of neurasthenia, psychoses, psychoneuroses, hysterias, and neuroses. These have in many cases a psychological basis, and can best be treated by the various methods of suggestion—hypnotism, psycho-analysis, dream interpretation, and

or in the combined tablets supplied by various firms. Adjunct or alternative. These may be given separately, and clearing away cellular infiltrations, is a valuable. The thyroid, from its power of detoxication, deaminizing, and opposite sex, but of this I have no personal experience, suggesting that the gonads act best if administered to the in high blood pressure deafness. Some work has been done reasonably and useful to employ ovarian or testicular extract though less definitely, to the male organs. It is therefore tending to rise in the female sex. A similar remark applies, these organs go out of office that we find the blood pressure of similar age. Alvarez attributes this to the controlling less common in women before the climacteric than in men. It is a remarkable fact that high blood pressure is much

opponent of the adrenals. important, because the pancreas is a well recognized stimulant the suprarenal capsules; and secondly, and more formation of toxic bodies in the intestine which over it assists in digestion, and tends to prevent thereby the Pancreatic extract is recommended for two reasons: first, in temperate as regards both food and drink.

business on their shoulders, and are apt to be somewhat successful commercial men who have the strain of a big that the male patients are usually, at any rate in the North, adrenal. The problem is made more difficult by the fact factor is an important one in the overstimulation of the mental strain and worry. Cannon has shown that the latter of bathing, exercise, and fresh air, and the diminution of animal foods and alcohol, attention to the general hygiene high enemies are of great value), reducing the amount of adrenal secretion by attention to the bowels (frequent large a hypoadrenalism. Measures must be taken to diminish the the gonads. The condition may frequently be attributed to the gonads. I have found most promising are the pancreas, thyroid, and several glands, or combination of glands, but it is worth as regards their general condition, but also as to the ears, on various hormone remedies. It may be necessary to try experiment such cases, generally speaking, do well, not only pathology of the condition, but I may say that in my is high, anything from 180 upwards.

There is not time in this short paper to discuss the whole is high, anything from 180 upwards. tion is generally negative, except that the blood pressure of not flushings and "done feelings." Physical examination of not flushings and "done feelings," when questioned, mature sensibility. The female type generally is of stouter build, past the menopause, and complains of signs of premature senility. At the same time the deafness is greater than is usual for his age, and we can detect no other signs of pre findings in cases of loss of conducting power in the auditory conduction, lowering of the upper tone limit, and the usual singing in his ears. Subjective tests show some loss of bone nourished, of full habit, inclined to stoutness, a good waller and golfer. He comes complaining of an annoying

outstrip them in their knowledge of psychology. For the sake of the children it was of the utmost importance that the psychological issue should be kept in a prominent position in their discussion. At Glasgow last year he suggested at a meeting of that Section that the General Medical Council should be asked to include the teaching of psychology and psychopathology in the medical curriculum, and the President of the Section, Professor Robertson, put forward a resolution on these lines which was unanimously adopted by the Section.

Dr. WILKINS pointed out that in the year 1926 additional school accommodation would have to be provided owing to the crop of armistice babies. Surely it would be advisable in every town of 30,000 people to provide an open-air day school. Nervous children improved immensely in such schools and did not cost the ratepayers an additional penny, as handstands, parks, sheds, verandahs, etc., could easily be used. It would therefore be quite possible to do something for the nervous children of the poorer classes in our day and generation.

Dr. L. A. PARRY (Brighton) thought that single children were much more often of the nervous type than children of big families. No people ought to marry if they intended to have only one child, for this only child never had a fair chance. He also suggested that children of Jewish families were very frequently of the nervous type. The difficulties of treatment were great, for in the large majority of cases the parent was so largely responsible for the condition of the child, and while it remained in the same surroundings the chance of cure was minimized. One thing in treatment was at all costs to be avoided, and that was psycho-analysis. He agreed with Dr. Potts that some form of simple religious instruction was very important in every child's life, but was very doubtful whether instruction in "the origin of life" was either wise or necessary, especially in very young children.

The Rev. Dr. BHABHA (London) asked Dr. Parry as to the class of Jewish children he had referred to as being "nervous," because in his work at a large East End charity clinic in London about 80 per cent. of the patients were of the Hebrew race. From his experience he had not noticed any pronounced evidence of the "nervous child" among them, while he had come across many cases of the Gentile children who could easily be classed as "nervous," and he thought that this was entirely due to the alcoholic habits of the Gentile parent.

Dr. PETER MACDONALD (York) said that it was with extreme diffidence that he ventured to take part in this discussion, and his sole excuse was the connexion made by Dr. Cameron, in his opening address, between postural defects and the other defects of the "nervous child," and between postural defects and other defects in the adult. He was going to put unorthodox views before the Section and, in particular, was going to take the unorthodox step of recommending to the Section the study of the work of a man who was not a medical man; and he did this solely with the hope that he might interest sufficiently some members of the Section, who were far more competent to have an opinion than he, to induce them to investigate his work. His name was F. Matthias Alexander, and Dr. Macdonald knew of his work through one of his books, *Man's Supreme Inheritance*, through another, *Constructive Conscious Control of the Individual*, which was at present in the press, and through his personal services to Dr. Macdonald himself and others; and he regarded his work as epoch making. As relating to the subject of this discussion, Dr. Macdonald had learnt from him or, rather, through him, three things: (1) That man did not now know

the erect posture, and possibly he had never learnt to acquire it consciously; (2) what the co-ordinated use of the muscular mechanism was, to secure the posture best for the moment; (3) and this was the important thing—he had learnt how to acquire knowledge of the co-ordinated use of such mechanism. As to (1), members of the Section would readily convince themselves if they would note, in observing their friends, that few of them who had reached the age of 50 had an abdominal girth which was less than their chest measurement, and that in those of their friends who were older they might observe a curvature of the top of the spine with the head carried downwards and forwards, which was usually considered to be the effect of old age. In all seriousness he asked the Section to consider if this might not be, not the effect of old age, but the cause of it. He said nothing about (2) at the moment, except that he denied point blank that the drill-sergeant's chest, which Dr. Cameron seemed to approve of, was a sound posture; and, indeed, in his out-patient department he took every opportunity, when the old soldier appeared, of pointing out his rigid protruding chest to his house-surgeon as the "characteristic military deformity." As to (3), it was an impossible task in a few minutes to do more than indicate Mr. Alexander's methods. Put shortly, however, by manipulation with his own hands he placed his pupil or parts of his pupil—his neck and chest, for example—in the posture he wanted him to learn; he painstakingly taught his pupil to allow him to do this passively; the pupil thus acquired a sense impression of the posture he wanted him to acquire; by repetition the pupil was enabled to register that impression and, once registered, he was able to reproduce it for himself. The reason for this method was that man learned a new thing only from experience, or, to speak paradoxically, he could not teach anyone anything except that which fundamentally he knew. Mr. Alexander's thesis was that man's control of his musculature, thinking processes, life functions generally, so far as they were subject to volition, was ordinarily an instinctive one; that instinct was a sound guide only in a stable or slowly changing environment, that in the rapidly changing environment of our developing civilization it broke down, and that for instinctive must be substituted conscious control. The effect of his training on health and disease was astounding, though he in no way professed to treat disease at all; he professed solely to be a trainer. Flat-foot became a trifling disability which simply disappeared. Asthma became ameliorated or removed; stammering was overcome; and Dr. Macdonald had seen a "nervous child," with much of the postural deformity Dr. Cameron had so ably shown in his slides, become a relatively supple, normal child.

## SECTION OF OBSTETRICS AND GYNAECOLOGY.

VICTOR BONNEY, M.S., M.D., F.R.C.S., President.

### THE RELATION OF SYPHILIS TO OBSTETRICS.

BY

C. S. LANE ROBERTS, M.S., F.R.C.S.,

Chief Assistant and Obstetric Tutor, St. Bartholomew's Hospital; Pathologist and Registrar, Soho Hospital for Women.

IN a brief paper on the relation of syphilis to obstetrics there will be no need to deal with the very controversial and theoretical side of the manner of infection. These remarks, which lay no claim to any original work, serve merely to emphasize the importance of rather going out of one's way to look for ante-natal syphilis, to urge thorough and efficient treatment of the condition when found or suspected, and to draw attention to the extremely good results accruing from such treatment.

By way of introduction a series of the generally accepted figures of the relation of syphilis to marriage may be of interest.

27,600 deaths occur annually in England and Wales ante-natally and in the first week after birth (Amand Routh).  
10 per cent. of all marriages involve a syphilitic individual.

75 per cent. of all offspring in a syphilitic family are infected (Jeans<sup>21</sup>), and 30 per cent. of pregnancies in such families end in death of the foetus at or before term.

40 per cent. of dead-born premature infants are killed by syphilis. 25 per cent. of all foetal deaths are caused by syphilis.

16 per cent. of stillbirths are directly due to syphilis (Eardley Holland).

Of syphilitic infants born alive 78 per cent. die in the first year, and of the remaining 22 per cent. many die in early childhood.

From Earle Moore's investigation of 200 cases,<sup>6</sup> of whom 178 had a positive Wassermann reaction and were pregnant, and 22 were non-pregnant mothers with syphilitic children, it was found that 22 per cent. had outspoken lesions of syphilis; in 72 per cent. syphilis was proved or strongly suspected by the history, physical examination, response to treatment, or subsequent course; in 21 per cent. all evidences of syphilis except a positive Wassermann reaction were lacking. Of the pregnancies in these cases, 41 per cent. proceeded to miscarriages or stillbirths and 20 per cent. gave living syphilitic children—that is, 61 per cent. produced syphilitic foetuses or children.

#### Modes of Infection of Mother and Child.

The more usual modes of infection may be classified as follows:

A. *Pre-natal infection of mother or child.* (1) The mother is syphilitic before becoming pregnant. (2) The mother is impregnated and infected at the same time, directly by the father. (3) At the time of impregnation the ovum only is infected, the mother either escaping or later acquiring the disease. (4) The mother being pregnant becomes infected.

B. *Intra-natal infection of the child.* A healthy child may be infected through a syphilitic genital canal.

C. *Post-natal infection of the child*—as by breast-feeding in a case where the mother was infected after the seventh month of pregnancy.

#### Relation of Syphilis to Ante-natal Supervision.

Most of the cases fall into one or other of the following groups:

A. *Manifested Disease.*—(1) In the mother, most commonly in the first or second stage. (2) In the foetus, according to Eardley Holland's investigation, from which he has classified them according as they show (a) signs of florid syphilis, (b) those with secondary attributes, (c) those with probable disease, (d) those with latent syphilis, in the group with "cause of death unknown."

In connexion with these cases Holland classed the evidence as primary, when the spirochaetes were found, and secondary in the following: (a) the maternal Wassermann reaction positive in 95 per cent.; (b) signs of syphilitic osteochondritis in 97 per cent.; (c) associated enlargement of the liver and spleen, of themselves of no value; (d) increased weight of the placenta; (e) typical histological changes in the placenta in 90 per cent.; (f) unequivocal syphilis in the mother; (g) birth of former known syphilitic foetuses.

B. *Latent syphilis*, from laboratory evidence of the Wassermann or Sigma reaction; and from examination of stillbirths, abortions, and placentae, or from probability according to the mother's previous history, with evidence of the father also or from previous children.

In connexion with latent syphilis it should be remembered that a history of primary or secondary disease is difficult and rarely possible; its absence is of no value. The obstetrical history is not reliable in any case, but all histories of abortion, stillbirth, neo-natal death, and later death should be gone into carefully to eliminate other causes. In the Wassermann reaction a positive one in any degree—that is, a 2, 3, or 4 plus reaction with an alcoholic antigen—demands antisyphilitic treatment, remembering that probably 1 in 100 normal people give a plus result, so that in unsuspecting cases a positive Wassermann reaction should be verified by a Sigma or a luetin test; in suspicious cases the Wassermann reaction of the father or of previous children should be taken, if reasonable evidence cannot be found to account for abortion, stillbirth, neo-natal, or later death, even if the blood test is negative, when a provocative Wassermann test and treatment should be instituted.

The examination of abortions is most disappointing, the spirochaete being rarely found even if the woman has had stillbirths crowded with them before.

In the examination of stillbirths Holland considers, in the absence of the spirochaete, when the maternal Wassermann test is positive, if the case falls into one of the four

groups, syphilis should be diagnosed: (a) with chondro-epiphysitis and typical placental changes; (b) chondro-epiphysitis with typical placental changes and enlarged spleen; (c) chondro-epiphysitis and enlarged spleen; (d) typical placental changes and enlarged spleen.

#### PROGNOSIS AS REGARDS MODIFICATION OF THE DISEASE AND EFFECT ON FOETUS AND FOETAL APPENDAGES.

A. *The Time during Pregnancy at which Infection Takes Place.*—Fournier's figures are as follows:

	Foetal mortality.		Morbidity.	
	Per cent.		Per cent.	
Pregnancy before infection	65	...	70	...
Conception with infection	75	...	90	...
Infection after conception	39	...	72	...

McDonagh thinks that if the disease is contracted before the end of the fifth month the child is bound to be infected; if at the fifth and sixth, half die, half do not; if at the seventh the child escapes, from which he makes the important conclusion that if the mother gets infected after the seventh month the baby must not be breast-fed to avoid the acquiring of the disease. It is generally agreed that the earlier in pregnancy the mother is infected the more likely is the pregnancy to come to an abrupt end.

B. *The Source of Infection.*—Fournier's figures are as follows:

	Foetal mortality.		Morbidity.	
	Per cent.		Per cent.	
Father alone	28	...	37	...
Mother alone	60	...	80	...
Both as source	68	...	92	...

C. *The Age of the Disease in the Transmitter.*—During the first year gives the worst prognosis; then during the next three years. Of a series of 90 women pregnant during the first year of the disease only two gave birth to living children.

D. *Parity.*—Multiparae show signs of greater resistance, and of attenuation of the virus, which may be due to their containing more natural protective substances with each succeeding pregnancy.

E. *The treatment*—as regards (1) its time of commencement; (2) the nature and thoroughness of it; (3) the patient's general condition—as, for example, the state of the kidneys. Boas,<sup>22</sup> in a series of 483 children born to syphilitic mothers, finds the treatment of the mother influenced the children as follows:

	No. of Children.	Syphilitic.	Non-syphilitic.
Untreated ...	153	157	1
Mercury before pregnancy ...	87	78	9
Salvarsan before pregnancy ...	15	12	3
Mercury during pregnancy ...	111	10	31
Salvarsan before, mercury during, pregnancy	26	7	19
Salvarsan before and during pregnancy	7	1	6

Findlay<sup>24</sup> in 15 pregnant syphilitics with treatment established early, obtained 14 living children; the fifteenth child died during a difficult labour; further, no signs of disease were found in the children up to 7 years of age, and the Wassermann reaction was negative in all but one, which became weakly positive at seven years. Galliot, in 144 cases treated with salvarsan during pregnancy, obtained only 11 non-living children, or 8 per cent. Adams<sup>23</sup> since 1917 had 136 cases with 4 deaths of children (at 3, 14, 36, 60 days) and 8 stillbirths, the last 108 cases with 1 death at the sixtieth day and 3 stillbirths, of these 2 occurring in cases that had had no treatment, and only came in just before labour.

#### Effect of Pregnancy on Syphilis.

A. *Alteration in the Wassermann Reaction.*—Whitridge Williams considers this test unreliable, as it may change in either direction during pregnancy spontaneously, or from day to day; and also because of the occasional occurrence of a falsely positive during pregnancy followed by a negative after labour, which may be a provocative reaction: falls suggesting this may be due to an excess of unbalanced lipid in the blood. The technique of the Wassermann test must be carefully studied, as results vary from different clinics; and again, for example, the ice-box method may be positive when the water-bath is negative.

B. *Protection from Manifestations.*—This may extend over a long period, and even with quite inefficient treatment several patients are clinically and serologically well.

that when complete rest of the larynx was required the patient should be instructed not only to keep silence, but also to refrain from forearm efforts. This paper, which is intended as a preliminary communication, as further researches are being continued by Mr. Negus upon the subject, will appear in the *Journal of Laryngology* and *Otology*.

Dr. J. A. Gibb (Maidstone) read a paper, derived from his own experiences, on the referred pain of nasal sinus pain did not appear to depend in all cases on the severity of the disease of the sinus. He detailed the areas for the various sinuses, and quoted cases illustrative of his thesis. This paper also will appear in the *Journal of Laryngology* and *Otology*.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### PAN-SINUSITIS AND SEPTIC THYROIDITIS.

The following case presents some features of interest, as the condition is comparatively rare; a somewhat similar case was recently reported by Sir Stclair Thomson.

A woman, aged 44, presented herself at the out-patient department of the Rochdale Infirmary on March 17th, 1923, complaining of severe occipital headache and marked tenderness of the thyroid gland. She stated that a year ago she became very susceptible to "colds," and shortly afterwards noticed some fullness of the lower part of the neck, in front. A week before attending at the infirmary she began to suffer from severe occipital headache and general malaise; the pain and tenderness of the thyroid gland began later in the same day. She had always been constipated. She looked acutely ill; the tongue was coated, temperature 100°. Pulse rate 118. The thyroid gland was enlarged, firm, and very tender. There was no complaint of nasal discharge and the nose was not examined. She was admitted that day. Treatment by local application of heat to the neck was adopted, but the symptoms did not abate.

On March 21st Dr. E. H. Cox exposed the thyroid gland by a vertical incision, but apart from slight oedema of the overlying tissues nothing abnormal was seen. The gland itself was explored with a hypodermic needle and from each puncture a small quantity of serous fluid was withdrawn. A small drainage tube was left in position and the wound sutured. The symptoms greatly improved. Three days later the discharge from the tube became purulent. Seven days after operation the temperature, which had fallen to 98°, rose to 102°, the severe occipital headache returned and was accompanied by tenderness of the thyroid gland despite the abundant purulent discharge. These symptoms gradually abated and on April 11th she was free from symptoms except for a slight serous discharge from the sinus in the neck. On April 16th the severe occipital headache returned and her temperature rose to 102.2°. After a brisk purge she was free from symptoms and the remainder of her convalescence was uneventful. On May 19th she was transferred to the out-patient department, as there was still slight discharge from the sinus in the neck. The fever and headache were treated on general principles, but throughout the illness great difficulty was experienced in keeping the bowels open. At no time during her illness did she complain of nasal discharge. The pus from the thyroid gland was not examined bacteriologically.

I had considered her infection to be of intestinal origin until I read Sir Stclair Thomson's article. I then immediately requested Dr. P. A. Harty, ophthalmologist and laryngologist to Rochdale Infirmary, to examine her. He reported that there was pus in both middle meatuses, mucopus in the left maxillary sinus, but none in the right, and that the anterior end of the left middle turbinate was enlarged and cystic. On June 28th he removed the anterior end of both middle turbinates and the anterior end of the left inferior turbinate. The anterior end of the left middle turbinate was definitely cystic and showed evidence of chronic inflammatory changes. He also curetted the ethmoidal cells and pus was present in the scrapings from both nostrils. The patient is at present under treatment by Dr. Harty; she informs me that apart from slight discharge from the sinus in the neck she feels perfectly well.

I submitted the facts of the case to Dr. Harry, and he considers the occipital headache and the thyroiditis to be due to an acute exacerbation of the chronic nasal sinusitis. The fact that the patient noticed the thyroid enlargement simultaneously with her susceptibility to "colds" is of interest, as this may explain the origin of some of the rare cases of so-called "idiopathic" chronic inflammation of the thyroid gland.

Acute Pan-sinusitis. *BRITISH MEDICAL JOURNAL*, June 2nd, 1923, p. 924.

## Reports of Societies.

### PULMONARY LESIONS OF INFLUENZA.

At a meeting of the Newcastle-upon-Tyne and Northern Counties Medical Society, held in the Royal Victoria Infirmary, Newcastle, on November 1st, with the President, Dr. R. BARNARD MOYSE, in the chair, Dr. A. F. BARNARD Shaw made a communication on "The pathology of the respiratory system in influenza," illustrated by a series of lantern slides showing the histological appearances of the lesions.

Dr. Barnard Shaw first referred to certain data regarding the disease which had emerged from historical study and observations made in the last pandemic. Certain of these data bore more or less directly on the remarkable series of changes found in the respiratory tract, and could be added as evidence of the possibility that influenza did not fall within the category of a bacterial disease. It had been shown that epidemics and pandemics of influenza had affected man since the fifteenth century and probably earlier. It had frequently been described as a "new disease." Its manifestations were extraordinarily protean. The phenomena of rapidity of spread was unlike a bacterial disease and in spite of the enormous amount of work done recently there was no definite proof of its bacterial origin. No one had succeeded in inoculating healthy men with the disease. Probably no other acute disease so greatly lowered the resistance of the body to infection by bacteria as influenza. In the fulminating cases, there was an intense tracheo-bronchitis with an aplastic exudate diffused throughout both lungs and necrosis of the epithelium at all levels of the bronchial tree. Later, localization of the process occurred together with a leucocytic reaction. At this stage there might occur as complications—acute bronchiectasis, abscess and gangrene of the lung. In those cases which survived a few weeks there was found extensive organization of the exudate leading to obliterative bronchiolitis, obliteration of alveoli,

### FACIAL PARALYSIS FOLLOWING HERPES

My thanks are due to Dr. Harry for his observations on the condition of the nose, and to Dr. Cox for permission to publish this case.

ANDREW ANDERSON, M.B., Ch.B., Glas.,  
House-Surgeon, Rochdale Infirmary.

The case of herpes with paralysis reported by Dr. Tombs (*BRITISH MEDICAL JOURNAL*, November 10th, 1923, p. 878) leads me to send the following notes of a similar case under my care.

On October 17th, 1923, I saw a Mrs. K., aged 50, who thought she had been bitten or stung by a small insect in the ear. She complained of intense pain on the right side of the face and forehead. I noticed some swelling of the external auditory meatus and surrounding tissues. The next day there was a very definite eruption of herpes involving the edges of the meatus and the concha, with complete facial paralysis of the affected side. The constitutional symptoms were severe: nausea, persistent vomiting, with severe headache and vertigo, and a temperature of 100.5° F. This went on for more than three days, and was accompanied by pain, sleeplessness, anorexia, and partial deafness (which, I venture to suggest, is due to paralysis of the stapedius muscle). No other lesion could be found to account for these symptoms.

This is clearly a case of herpes facialis with facial paralysis, and the paralysis is still fatal at the end of nearly four weeks. One point is, I think, of interest in view of recent controversies on the subject—namely, the incidence of some cases of varicella in the village at the same time.

During the last two years I have observed four cases of herpes zoster in the same village, which were also coincident with an epidemic of varicella; one, a case of exceptional severity, actually occurred in the father of a child suffering from varicella at the time.

MONAGHAN LAWRENCE,  
L.M.S.S.A., Lond.

Sharnbrook, Bedfordshire.

C. *Disturbance in Time Relations of the Three Stages.*—Chancres and secondaries coexisted in a series of 9 to 32 cases. Sometimes the secondary stage may be delayed ten months. The interval between first and third stages may be much shortened.

D. *Alteration from a Typical Response to Infection.*—There may be suppression of all early lesions, especially when there is simultaneous impregnation and infection; or the lesions may take a milder form. Sometimes when conception occurs with infection, or during the florid stage, the disease may take a graver form; the chancre may be larger, hypertrophied, more moist, with a tendency to ulceration, and to become phagedenic, and may last longer, up to three months. In a series of 11 cases of chancre, one lasted one month, and the average was two and three-quarter months. The secondary manifestations may come sooner, be more marked owing to the local succulence, the exanthem widespread, papules larger, pustules common, more tumefaction of glands, with more tendency to suppuration. Of these florid cases Fournier says that eroded papules are numerous on the vulva, they develop in a singular exuberance, take on quickly a granulating appearance, hypertrophy, and often constitute veritable tumours, which invade and entirely deform the entire vulva. Further, they are always more rebellious to treatment, being reabsorbed slowly and with difficulty. The ulcerating syphilides are very frequent in pregnant women, are livid, purple, and excavated, which condition is increased by the general tumidity of the parts. They persist longer and have a tendency to become phagedenic; the anaemia is more profound, the fever more common and higher; neuralgias occurring soon after marriage may draw attention to the condition. Tertiary syphilis is less affected by the advent of pregnancy, though the latter may sometimes awake the disease which was thought to be cured. Most who get impregnated and infected at the same time are singularly free from remote grave manifestations. The resistance of the individual is considerably lessened if there is any systemic weakness, especially tuberculosis, or disease of the circulatory, kidney, and endocrine systems.

E. *Production of a Symptomatic Neuro-syphilis.*—In a large series of 5,400 syphilitics (54 per cent. men and 46 per cent. women)\* 20 latent disease was found to be twice as frequent in the latter, and 42 per cent. of these were pregnant. Junius considers 50 per cent. of paretic women to be sterile. Contrary to that which happens in men, a mild early syphilis does not lead to a neuro-syphilis in women. Half the women showing clinical neuro-syphilis have not been pregnant since infection. Multiparae are less liable to asymptomatic neuro-syphilis than primigravidae. Pregnancy probably accounts for the freedom of women from neuro-syphilis. The cerebro-spinal fluid is abnormal twice as often in the sterile as in those with one or more pregnancies, in cases of late disease—that is, longer than one year. The following figures show the ratio:

	Men.	Women.
Cerebro-spinal syphilis ...	2.5	1
Tabes ...	6.3	1
General paralysis ...	4.2	1
Meningitic neuro-syphilis ...	2.2	1
Vascular neuro-syphilis ...	4.7	1

Sir Frederick Mott's figures<sup>9</sup> show a remarkable difference in the birth rate of male and female tabetics and tabo-paralytics—a series of 24 such women having had only three living children, and of 54 such men 151 living children, and both the same number of miscarriages and children born dead—namely, 51.

#### Effect of Syphilis on Pregnancy.

The patient herself often suffers more, the ordinary subjective discomforts of pregnancy being aggravated—as headaches, neuralgias, insomnia, all of which are improved by anti-syphilitic treatment. If a woman who has syphilis becomes pregnant the following events may happen:

1. The foetus may die, giving an early abortion. Ruge considers that of repeated abortions 83 per cent. are due to syphilis.
2. More often a late abortion, at the fifth to the seventh month, or an early premature labour, at the seventh to eighth month.
3. The foetus may die, and be expelled prematurely, with either positive or negative signs of syphilis in the foetus and placenta.
4. The child may be born at term healthy and may continue free from disease.
5. The child, born at term apparently healthy, may develop signs of disease six to eight weeks later.
6. The child at birth may show neo-natal syphilis—for example, pemphigus, mucous tubercles round the anus, etc.
7. The child born at term may show no distinctive symptoms, but soon appear haemorrhages, jaundice, extreme debility, changes in skin, intestines, and viscera.

8. The child may exhibit congenital manifestations, microcephaly and hydrocephaly, delayed development of teeth, spina bifida.

9. There is also syphilis hereditaria tarda, evidenced by interstitial keratitis, deafness, bone, skin, and visceral lesions; or the children are stunted, with Hutchinsonian teeth, saddle-shaped noses, and linear scarring round the mouth; or infantilism, or subsequently developing general paralysis, tabo-paralysis, primary optic atrophy, and epilepsy.

#### Effect of Syphilis on the Labour.

Many cases are normal. Others have malpresentations owing to the prematurity or to the maceration of the foetus. At times there is primary uterine inertia with weak contractions.

A "wooden" cervix may be present, which may feel as hard as a ring pessary, so that incisions may be needed to deal with the oedema and induration, as the membranes at times rupture early in such cases, for often chancres and secondary ulceration cause much induration. Instruments may be needed owing to maternal exhaustion and foetal asphyxia. There may be outlet troubles, with tertiary swellings and ulceration, being either rigid or tearing like wet blotting paper; these cases being useless to suture, but healing best by granulation, with anti-syphilitic treatment. There is often less tendency to post-partum haemorrhage, for if the foetus is dead there is generally thrombosis of the placental site. Rarer events have been recorded, such as rupture of the rectum above a stricture, rupture of the heart with a sudden rise of blood pressure, aneurysm of the uterine artery with rupture, spontaneous rupture of the uterus, and some cases of premature separation of the placenta.

#### Effect of Syphilis on the Puerperium.

There is no particular increase of mortality or morbidity, except with maceration of the foetus and premature rupture of the membranes. Subinvolution is much controlled by anti-syphilitic treatment. Some figures on the incidence of pyrexia may be added:

	Normal. Per cent.	Syphilitics. Per cent.
Pyrexia in labour ...	2.7	2.2
Pyrexia in puerperium ...	20.0	19.0

#### EXPERIMENTAL EVIDENCE.

Brown and Pearce<sup>11</sup> on the relation of pregnant and lactating women to inoculation with *Treponema pallidum*, from experiments on intradermal genital inoculation of pregnant rabbits, decided that the effects when inoculation coincided with conception are very different during pregnancy and well on in lactation. Normal female rabbits react by prompt development of characteristic primary lesions and lymphadenitis, but of 8 pregnant rabbits so inoculated only 4 showed any clinical signs, 3 very slight and transient with no lymphadenitis, only one that gave rise to lesions at all comparable to the normal being inoculated at the middle of pregnancy, followed by a long latent period of fifty-four days, compared with the normal of ten.

On the pre-natal transmission of syphilis,<sup>12</sup> in all probability an intimate relationship exists between the involvement of the testicle and transmission of the disease to wife and progeny, for animal experiments show that the testicles of apes are found to be infective even when inoculation with spleen and bone marrow failed; that testicular inoculation in rabbits with *Treponema pallidum* produces a high percentage of positive results, whereas with intravenous inoculation into the cornea in the same animals the percentage is considerably less; that intravenous inoculation in rabbits failed often to produce lesions other than those of scrotum and testicle; and that the bone marrow and testicle have been seen to show the treponema before the chancre.

Various hypotheses have been suggested to explain the protection of pregnant women from syphilis. Generally during pregnancy women are more resistant to chronic infections; but in no other disease than syphilis does this protection extend over a number of years, so that the factor of pregnancy supplies some substance which is often able to suppress the manifestations of the disease even when inoculation occurs by the usual route. It seems that greater protection is afforded against protozoa than against bacteria, and against human cells than against protozoa, so that it is possible that chorionic particles are very active against syphilis; and in a case of conceptional syphilis the infection is milder, for the protective substances are augmented by the chorionic protein colloidal particles, which act at the site of infection.

It is along this line that Amand Routh has worked out his theory of the protective action of the chorionic ferments in pregnancy; and following Noguchi's observation on spirillo-lysis of the organism of syphilis, he has suggested, to explain the agent which Nature has provided for this spirillo-lytic action, that the chorionic ferments or syncytial toxins or their derivatives have this granulating power; and further, that they have the continued action on these granules, rendering them latent and biologically inactive, and perhaps in a few cases destroying them.

#### ANTE-NATAL MANAGEMENT.

In regard to the types of mother attending the clinic, Sequeira mentions three classes: (1) Those with a history of one or more miscarriages and no sign of active disease; a Wassermann test should be taken. (2) Those with active syphilis. (3) Primigravidae, with no signs; should a Wassermann test be taken probably one in a hundred normal women without syphilis would give a positive result. In some ante-natal clinics a blood test is taken of all patients. A positive Wassermann in this group should be verified by a luetin or Sigma reaction. In a suspicious case the Wassermann test of the husband and of any previous children is taken, and if any of them are positive the woman should be treated.

In the investigation of patients all these groups should be carefully gone into, with a detailed past history, remembering Beck's statement<sup>27</sup> that only 18 per cent. helped by their own history or by a physical examination, but 60 per cent. helped by the previous history of miscarriage, stillbirth, living syphilitic infants, or a tendency to carry each successive pregnancy further. A very close record should also be kept of all miscarriages and stillbirths, and all those due to syphilis determined.

#### Difficulties of Diagnosis in Women.

The elusiveness of the history, and frequent modification of the course of the disease, are common difficulties. A number of cases of congenital syphilis pass, especially in women, run latent course, and are not recognized. Congenital syphilis in women and in the third generation has an especial tendency to run a mild latent course, sometimes without any clinical sign or symptom. Many women acquire syphilis without recognizing any of the earlier stages, through ignorance or because the early symptoms are slight or entirely absent. It should be remembered that mothers admitted with gonorrhoea often have syphilis as well: a Wassermann test should therefore be taken in cases of gonorrhoea. Those with a suspicious history should in some cases be given a luetin skin reaction and a provocative Wassermann test, some a test of the cerebro-spinal fluid. A Wassermann test is regarded as positive when a 2, 3, or 4 plus reaction with an alcoholic antigen is obtained.

#### Points in Connection with Treatment.

It is never too soon or too late to give the initial injection—either before the woman becomes pregnant if possible, or within an hour of the commencement of labour. Though a few are refractory, most pregnant women are extremely amenable to treatment. Surprising results occur from apparently very inefficient treatment, and almost ideal results follow from efficient treatment. Every syphilitic woman should be treated during pregnancy with salvarsan, though she may have undergone previous systematic treatment, a negative Wassermann reaction or only very old-standing disease being no objection.

#### Precautions in carrying out the Treatment.

Avoid pain as much as possible, or the patients will not come back, and it is difficult enough to induce them to continue treatment as it is. Watch the urine carefully for signs of albuminuria. Continue the mercurial treatment till there are signs of increased salivation. Take great care of the teeth, attending to dental sepsis early in pregnancy. If intravenous medication shows signs of too rapid absorption, the treatment need not be discontinued, as bad symptoms do not appear again if intramuscular injections be given instead.

#### Routine of Treatment.

A. For those cases in which there are primary or secondary signs present. Each clinic will have its own plan of treatment of an ordinary case of syphilis, and it is always most satisfactory to give the course on the premises where the woman is going to be confined.

B. For those cases of latent disease in which no primary or

secondary signs can be found. At the Leeds Maternity Hospital a routine suggested by Colonel Harrison is being used with most satisfactory results. Weekly injections of neo-kharsivan, starting from 0.3 gram, being given, increasing up to 0.6 gram with weekly rests at the 4th, 7th, 10th, 11th, 12th to 21st, 26th to 28th weeks; hydrarg. cum creta, grain 1, being administered thrice daily all the time; potassium iodide, grains 7 to 10, thrice daily during the 10th to 12th and the 26th to 28th weeks.

C. Post-natal treatment is most important, being combined with the breast-feeding, and the case should be followed if possible for two to three years after the Wassermann reaction becomes negative, remembering that some never become negative.

#### THE SYPHILITIC INFANT.

The newborn syphilitic child may be healthy, showing no signs for six weeks or more; or he may be the typical old man, small, wizened, atrophied, puny, weakly and sickly, skin flabby, wrinkled, and of a brownish colour. He may have oedematous limbs and face, and a large abdomen, with bad circulation and a bluish tinge all over, and appear as if going to die, and will certainly do so if left untreated. He usually shows signs if untreated in the first month, and 80 per cent. of syphilitic children shown signs before the end of the second month. Practically all show signs of syphilis before six months, most of the mother's being in the secondary stage of syphilis, only a tenth of them having the primary condition. The child may show no signs at all except progressive and unaccountable loss of weight, indeed losing many ounces in a day or so, and as suddenly stopping with the institution of antisyphilitic treatment.

#### Points in Management.

1. Every infant of suspected parents should have a Wassermann test taken at birth, and again on the tenth day, when the result is more reliable; then every four weeks up to six months, then every three months to two years.
2. The type and time of infection should be carefully considered—as, for example, there is no need to treat a child where the mother has been infected during the last two to three months of pregnancy, if the Wassermann test is satisfactory.
3. Infants with one or both parents giving a positive Wassermann reaction should, if the infantile test be negative, be carefully watched, and probably should be treated if there is any ground for suspicion at all.
4. If any clinical signs appear, even though the infant is serologically negative, treatment should be established.
5. The Wassermann test has to be very carefully and delicately done, using cholesterolized extracts for antigens.
6. Some recommend other reactions—for example, luetin for children, sometimes with a provocative Wassermann test.
7. In a series of 1,500 ante-natal patients, 13 per cent. were diagnosed as syphilis by the positive Wassermann test only, and verified by the luetin reaction in 50 cases, giving a pustular reaction in 77 per cent. of these.
8. Drugs should not be injected into the superior longitudinal sinus nor blood taken from it; intramuscular injections and Adams's bayonet needle for taking blood from the heel give very satisfactory results, and are extremely simple of management.
9. The average number of galyi injections needed to get a positive to a negative is 10.
10. In some cases salvarsan must be given within an hour of birth.

*Principles of Management.*—At birth blood is taken from the mother, placenta, and child for testing, though in infants a positive reaction is of little value as proving congenital syphilis.

All children with negative Wassermann reaction at birth keep so for ten to twenty months. Of positive children at birth most are negative between three weeks and twenty months later.

The Wassermann test is less reliable from the infant at birth than on the tenth day. In 1,000 unselected cases there was a positive Wassermann result in 10 per cent.<sup>30</sup> Salvarsan and mercurial treatment has a more certain and quicker action in producing a negative Wassermann reaction in children than in mothers.

#### Routine of Treatment.

Many methods of treatment have been outlined, but mention only will be made of that line of treatment along which Mr. John Adams works at the Thavies Inn Clinic with such conspicuous success.

the change in the blood sugar produced by insulin injections, emphasizing the importance of giving the dose at meal times. No evidence of permanent cure had been noted, but the response to the drug became more evident as treatment proceeded. In some cases insulin treatment had no advantage over dietetic treatment; in others it was vitally necessary. He urged that the preparation should be provided free for poor patients.

Dr. G. Brewster, referring to blood sugar estimations, said that he himself had little difficulty in accurately measuring the amount of blood required, but that as a point of technique he would like to know whether the length of time taken in bringing the solution to the boil, and the length of time of boiling, made any difference in the results. While diabetic coma was best treated by insulin, it was important to remember that some cases did very well under complete starvation. Among the various patients whose blood sugar he had estimated the most interesting was one in whom he found a blood sugar as high as 0.55 per cent. without sugar appearing in the urine. It was stated that in progressive diabetes the threshold value was often raised, but he thought the one he now reported—0.55 per cent.—was the highest yet recorded.

Dr. W. Deason remarked that the metabolism of glucose was quantitatively the most important biochemical reaction in the animal body, since the greater part of the normal diet was composed of carbolic drates, and the carbolic drates were absorbed chiefly in the form of glucose. The glucose concentration of normal blood was regulated by the rate of its absorption from the alimentary canal, by the renal threshold mechanism, by the glycogen condensation mechanism, and, lastly, by the rate of its removal by the tissues. The characteristic effects of insulin were manifested in the last of these operations. The administration of insulin caused glucose to leave the circulating blood. It was not rapidly burnt away or condensed to glycogen, and Alcolac considered its disappearance to be due to its absorption by the tissues, which developed a "glucose vacuum." Insulin appeared to have no special action on glucose in simple solutions, the presence of the tissue cells being an essential factor. If insulin were administered alone it sooner or later exhausted the glucose reserves of the organism, the blood sugar fell, with characteristic results. When the blood sugar value reached about 0.075 per cent. in the human subject the patient experienced extreme hunger, fatigue, and vasomotor discomfort. Insulin, whatever its ultimate value might be in the prolonged treatment of diabetes, was a specific for coma arising from ment of diabetes, since by its action on glucose it supplied the missing factor necessary for the complete combustion of the fatty acids.

Dr. H. F. Moore said that it was clear that diabetes was a deficiency disease in relation to the supply of insulin from the islands of Langerhans. All treatment should be so planned that the blood sugar be kept within normal limits. The fasting blood sugar should not be greater than about 0.1 per cent., and the blood sugar during digestion should not rise to a point greater than 0.16 per cent. This meant that the diet upon which the patient lived must be rather exact, and to this dietary the dosage of insulin should be carefully correlated. It was probable that the majority of diabetics did not require insulin; with dietetic treatment alone it was possible to abolish the glycosuria and to bring the blood sugar to normal without actual starvation, by keeping the patient on a so-called "basal" diet with a low content of carbohydrate and fat. This method succeeded in accomplishing the desired result within two to six days, depending on the severity of the case. Only the unusually severe cases required fasting to get rid of hyperglycaemia, and these generally could not, without hyperglycaemia, use a diet upon which they could exist unless they got insulin. The final diet in all cases should be sufficient for the patient's requirements in calories and it should be properly balanced in its proportion of carbohydrate and fat in order to avoid acidosis. The disadvantages of insulin treatment were: (1) Subcutaneous injections for long periods of time; (2) the cost; (3) the frequency of slight local reactions, undoubtedly due to protein impurities, which should become less frequent as the methods of preparation of insulin improved; and (4) the danger of hypoglycaemic reactions.

## EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

The Medico-Chirurgical Society of Edinburgh met for its first meeting of the hundred and third session on November 7th, with the President, Sir Robert Poirer, in the chair. The officials for the current session were elected, C.M.G., F.R.C.S. Edin.

Professor Lewis Braxwell showed a boy, aged 11, suffering from Thomson's disease. He thought this was the first case of the kind which had been demonstrated to the Society. It was a rare condition and he had only met four cases in twenty-three years. Professor Braxwell demonstrated the striking characteristics of the disease: (1) difficulty in muscular relaxation until the movement had been frequently repeated; (2) hypertrophy of groups of muscles. The boy had a rounded face due to enlargement of the masseters and showed beautifully the difficulty in opening the eyes after closing them firmly. The calf and shoulder muscles showed definite enlargement and the relaxation spasm in the hand was well marked.

Mr. J. W. Struthers brought before the Society a case he had previously exhibited—a man with a symmetrical swelling in the left frontal region. In the interval the case had been operated upon. The condition before operation appeared to be a tumour growing from the membranes and invading the frontal bone. The tumour had been removed and the man was now back at full work. Lantern slides illustrated the tumour both clinically and by x rays. The tumour was an endothelioma.

The retiring president, Sir Robert Poirer, before vacating the chair delivered his valedictory address. He read the work over taken by the Society, remarking sketched the variety and high standard attained in the papers on the variety and high standard attained in the papers read. He mentioned the increased membership, and that the Society had honoured itself by admitting to its "corresponding membership" ten distinguished colleagues from Europe, America, and England. Grievous losses had been sustained by the death of many distinguished ordinary members—Sir James Affleck, Dr. Ballantyne, Professor Boyd, Professor John Chiere, Sir Halliday Croom, Dr. Harry Rany, and others. Apart from the ordinary meetings the Society had had the privilege of welcoming and listening to addresses by Professor Calmette, Professor Bordet, and Professor Pirquet. During his occupancy of the chair Sir Robert had noticed that short crisp papers were more apt to awaken discussion than did the lengthy orations. Spontaneity of discussion should be attained, and when this was followed the members got nearer the heart of the matter which was under consideration. When he joined Littlejohn occupied the chair, the vice-presidents being Sir Thomas Fraser, Dr. David Wilson, and Sir John Barry Tuke. They, and other officials of the Society, had passed away, but it was remarkable to note that almost 45 per cent. of the officials of forty years ago remained in vital connexion with the old Society.

A. Blood is taken for the Wassermann test at birth, on the 40th, 80th, 176th days; then every two months up to two years; then less frequently up to seven years, according to the progress of the case.

B. Intramuscular galyi in glucosa is given in doses of 1.25 cg. to 3.5 cg., on the 8th, 22nd, 36th, 50th, 64th, 78th, 120th, and 134th days; at the 9th and 12th months courses of three injections of 4 to 5 cg. galyi and 1/2 grain mercury should be given and hydrarg. cum creta, grain 1, daily for a month.

C. Intramuscular mercury is given on the 8th, 22nd, 36th, 50th, 64th, 78th, 120th, and 134th days; from 1/6 grain to 1/3 or 1/2 grain of hydrarg. cum creta is crushed up in the feed, at first daily then twice daily.

D. Further treatment is governed by the progress of the case; should the Wassermann test become positive at any later date intensive treatment should be begun immediately.

E. Breast-feeding should be the rule, remembering that the milk of a syphilitic mother is often deficient in quality and quantity, so that it may be necessary to supplement it; also that infection of the mother after the seventh month is a contra-indication to breast-feeding, for then it is agreed the baby will be born healthy, and as the spirochaete has been found in the milk of nursing mothers, the infection would easily be passed on to the child.

Fordyce and Rosen<sup>24</sup> had a series of 140 cases of children, born of mothers with + + + Wassermann; 88 had evidence of syphilis, the Wassermann was positive in all, and clinical manifestations in 20. All were treated with neoarsphenamin and mercuric chloride, with good results.

Mr. John Adams's figures obtained at the Thavies Inn Clinic show the following extremely satisfactory results:

Years.	No. of Mothers with Syphilis.	Babies Alive.		Babies Dying.	Stillborn.
		Wassermann Reaction			
		Positive.	Negative.		
1917-18	23	17	6	3	5
1918-19	30	8	21	1	1
1919-20	37	1	36	0	0
1920-21	23	5	16	0	2
1921-22	18	7	9	0	2

It is hoped that figures will soon be forthcoming of the results of the following up of such cases to puberty, so that a clear idea may be obtained of the real benefits accruing from treatment which has been efficiently carried through, in the campaign against the protean phenomena of congenital syphilis. Finally, I may urge, in the words of Dr. Sequeira, the importance of co-ordinated effort; the ante-natal clinic, the infant welfare centre, the children's clinic, and the venereal clinic must work in co-operation, and then we can hope to see the passing of congenital syphilis.

The writer is very much indebted to Mr. Adams of the Thavies Inn Clinic for his kindness and courtesy.

## ROENTGENOGRAPHIC PELVIMETRY.

W. R. MacKENZIE,

Surgeon, Samaritan Hospital for Women, Belfast, Ulster.

THE addition of roentgenography to our obstetrical resources enables us not only to see the size and shape of the mother's pelvis and of the foetal head, and the relations of the one to the other, but also to measure the pelvic diameters, both of the inlet and the outlet, without vaginal examination. Since the existence of contracted pelvis was first reported by Arantius various methods have been employed for diagnosing the existence and measuring the extent of the pelvic deformity.

External pelvimetry, introduced by Baudelocque, while enabling us to measure directly the external pelvic diameters, and thence to draw certain conclusions as to the degree of contraction, is insufficient for estimating the size of the pelvic cavity. This cannot be done directly in the living woman, except by a laparotomy. Every obstetrician has encountered cases which appeared on external examination to be normal, but when labour was advanced unlooked-for difficulties presented, when it was too late to do an abdominal operation. In the same way one meets cases where there is external pelvic deformity and where one anticipates a difficult confinement, but in which, on the contrary, labour is quite unobstructed and the infant is of average size.

Internal pelvimetry—a method devised by Skutsch—made it possible to estimate the size of the pelvic cavity indirectly and with fair accuracy, but the employment of his instrument necessitates an anaesthetic, if discomfort or actual pain to the patient is to be avoided.

The Roentgen rays, it was thought possible, might afford a valuable method of investigating the size and shape of the pelvis, but it was found that, while an excellent idea as to shape was obtained, that as to size was erroneous, owing to the fact that the sacrum and pubis lay at different levels from the sensitive plate, and consequently one portion of the pelvis was enlarged out of all proportion to the other. This defect made it impossible to utilize radiography for purposes of mensuration.

The employment of the following method will obviate this difficulty and make it possible not only to see the existence and extent of the pelvic contraction both of the inlet and the outlet, but also to compare the pelvis under examination with the normal pelvis, and to measure its diameters without causing any appreciable inconvenience to the patient.

#### Position of Pelvis.

Before discussing the technique of this method of pelvimetry a few anatomical facts on the position of the pelvis should be noted. In the erect posture the pelvis is placed obliquely with regard to the trunk of the body. The base of the promontory of the sacrum, in well formed females, is nearly four inches above the upper border of the symphysis pubis.

The plane of the pelvic inlet, or true conjugate, forms an angle of about 65 degrees with the horizontal plane. Therefore with an anterior vertical plane it will form an angle of about 25 degrees. If the plane of the inlet is bisected by a line at right angles, one extremity will pass through the middle of the coccyx and the other through the umbilicus. The axis of the pelvic inlet is therefore directed downwards and backwards.

#### Technique.

The patient lies flat, face downwards, on the table with her symphysis pubis touching the plate carrier. The x-ray tube is raised two feet above the plate and focused on a point four inches below the mid-point of a line joining the posterior iliac spines; this point corresponds to about the middle of the coccyx. The tube is then tilted forward through an angle of 30 degrees, towards the patient's head, and it will then lie parallel to the plane of the pelvic inlet. The rays will thus be directed upwards and forwards in the

\*An article by Dr. MacKenzie on roentgenographic pelvimetry with illustrations of the types of pelvis was published in the BRITISH MEDICAL JOURNAL of June 1st, 1913, p. 612.

first distinguished clearly by Munro and elaborated by Haslund, showing that the primary lesion was a cell infiltration into the rete and accumulation beneath the cornuous layer—a microscopic abscess; later, parakeratosis, or retention of nuclei, occurred here and there in the cornuous layer with collections of striated leucocytes, and acanthosis, or proliferation of the rete cells, was abundant, while in the cornium there was widening of the vessels and accumulation of leucocytes round them.

The pathology of psoriasis was unknown, investigators attributing it variously to a parasite, to a fault of metabolism or the nervous system, or to one of the great systemic infections, tuberculosis or syphilis. Schamberg and his collaborators attempted to find a parasite, using complement fixation methods and culture media of all varieties, with but without the patient's serum, extract of the scales, etc., and they were unable to isolate anything but the ordinary skin bacteria. Dark ground illumination showed what appeared to be a bacillus, but Keiron later brought evidence to prove that this was a *B. brin* form. Inoculations on animals were equally unsuccessful. They also investigated the metabolism in psoriasis, using the amounts of nitrogen ingested and excreted as an index, and were able to prove that nitrogen retention occurred, but Tidy later showed that this occurred also in exfoliative dermatitis. It was now believed that this retention was due only indirectly to the disease and depended on the degeneration. While there was evidence for a parasitic origin was negative, there were no features which seemed to point to any other hypothesis which could not be equally well explained if the existence of a parasite were assumed. The microscopic anatomy and the spread of the spots by peripheral extension were strongly in favour of this, but it was necessary to predicate a predisposition—namely, a suitable soil.

Treatment had only a temporary effect. Locally, after removal of the scales, the tars, mercaptans, and the chrysarbin group (including pyrogallol and resorcin) were the applications most used. Mercaptals were the least and chrysarbin the most effective. Any application should be rubbed in. Chrysarbin was not an antiseptic, tested against staphylococci, *arobis* being that of a reducing agent, but its special value compared with other reducing agents depended on its stability, so that it was at full strength when applied, on its ready oxidation by proteins and their derivatives, and on the fact that sodium chrysarbinate or other product of oxidation was quite innocuous. Sunlight, the electric arc, and x rays were all useful in special cases.

The internal treatment was marked by the variety of the drugs used and the uncertainty of their action. These fell into six groups: (1) the arsenic group (including antimony); (2) the heavy metal group—mercury and manganese; (3) the iodides and thyroid; (4) carbolic acid, tar, and the volatile oils; (5) alkalis and salicylates; (6) vaccines and auto- and hetero-serums. Arsenic was the most reliable and was usually successful in first attacks; it should be pushed to tolerance. Hypodermically or intravenously seemed best, salicylan being generally unsuccessful. Mercury and manganese were given hypodermically. The iodides were reserved. Salicylates had been given in large doses intravenously and salicin by the mouth. Vaccines, usually of staphylococci but often of other bacteria, might be effective. Discussing these drugs, Dr. Beatty pointed out that no physical or chemical relation between them could be discovered, and that they had to be administered in full doses. He believed that a pharmacological relation existed, for they were all tissue poisons—even serums, since symptoms resembled anaphylactic poisoning could be produced by first treating serums with physical agents. He strongly advocated the view that the really active body was some product of protein breakdown, and believed that this was true also of the treatment of syphilis, where unrelated substances like arsenic, antimony, bismuth, mercury, and even iron spirochaetes in *vitro* might be explained in this way. The treatment of both psoriasis and syphilis seemed really a chronic poisoning, and the cure only indirectly due to the drugs used.

Sir Robert Philip reminded members that it was more than a hundred years since the Society was founded, and subsequent recognition had hardly been bestowed on the first president—Andrew Duncan—who was largely instrumental in originating the Society. He was "divinely thrilled, exultingly full, as quick well waters that come of the heart of earth." He succeeded James Gregory in the chair of the practice of medicine in the University, was twice president of the Royal College of Physicians of Edinburgh, being recalled to occupy the chair in 1824, when 80 years of age, as a tribute to his inexhaustible, untiring devotion to the interest of others. His interests were wide. He was a keen botanist, loved his garden and proposed the establishment of a public experimental garden. He was singularly responsive to the delicate vibrations of art and his story of his discovery of Henry Raeburn—afterwards Sir Henry Raeburn—and the lifelong devotion to the great artist reads like a romance. Raeburn's last game of golf was played when 67 years of age—five weeks before his death—with Andrew Duncan, who was in his 80th year. In conclusion, Sir Robert said:

"At times it is good to fall back intimately on the past. It is good for us to recall the men who sat in those places before us. It is good to be reminded of what sort they were. Our Society comes of noble ancestry. Its creator and first president was a man of fine fibre, clear brain and large heart. He had a big conception of the possibilities of the Society. A man who lectured on the practice of medicine during fifty-three consecutive sessions and at the same time, swept the human horizon as he did, so that his name in the Royal Public Dispensary is justly inscribed with the words 'Benefactor of his species,' and one who played golf and climbed Arthur's Seat when well over 60, was made of the right stuff. His reading of life and the uses of a medical society afforded abundant food for reflection. The balm, which two years ago was received by me at the hands of one distinguished surgeon, I now pass to another, with the certainty that he will wield it wisely and well. *Sic ut patrum, sit Deus nobis!*"

A cordial vote of thanks was proposed by Sir David Wallace and seconded by Professor William Russell.

Mr. Henry Wade gave a lantern demonstration entitled "The clinical significance of the form and capacity of the renal pelvis." Certain anatomical points about the normal renal pelvis were illustrated by casts made of fusible metal. He then referred to his own *post-mortem* findings while he was an assistant pathologist at the Royal Infirmary about fifteen years ago. X-ray photos were thrown on the screen showing the capacity of the renal pelvis by means of pyelography and the technique of the procedure was discussed. Clinical examples of the following conditions of congenital abnormalities were demonstrated by x-ray photos—namely, single functioning kidney, horseshoe kidney, congenital cystic kidney, pelvic kidney, and unilateral fused kidney. Pathological states of the kidney were also demonstrated, such as hydronephrosis, pyelitis, suppurative pyelonephritis, tuberculous disease, renal calculi, and tumours.

The demonstration was discussed by the President, Dr. Chalmers Watson, who referred to the value of such methods in medical cases showing bacteria; Sir Harold Stiles, who hoped every facility would be given Mr. Wade for pursuing this line of study; and Dr. W. A. Alexander, who quoted his findings of congenital abnormalities in a series of 500 consecutive necropsies.

Dr. Beatty read a paper on psoriasis.

At a meeting of the Cardiff Medical Society held on November 15th, with the President, Mr. William Martyn, in the chair, Dr. J. Beatty read a paper on psoriasis.

Dr. Beatty said that as the disease was familiar he did not deal with its symptoms and course beyond emphasizing the extremely small size of the initial lesion, the fact that the spots grew at different rates, and that new spots might occur while others were fading; it occasionally occurred at the site of wounds or superposed on other skin diseases where there was a breach of surface, and it persisted indefinitely, recurrence being the rule. Psoriasis was related to ill health, for the dictum that it was a disease of the healthy applied to about one-third only of the cases; it was not contagious, though very rare cases of apparent infection had occurred. He described the microscopic anatomy as

berating mildity;  
berating temperatu  
orage temperature

axis of the true conjugate, and an excellent image of the pelvic cavity will be obtained on the plate.

In this technique there are three constant factors:

1. The point of focus.
2. The x-ray tube at the same angle to and at the same distance from the sensitive plate.
3. The relation of the symphysis pubis to the sensitive plate.

Having these three fixed points and using the shadow of the symphysis pubis as an axis we can accurately measure any object within the "tube radius."

The possibilities of error in interpreting the size of the inlet, because of the varying degree of tilting of the different pelves, are negligible in this method of pelvimetry. In a contracted pelvis the angle which the plane of pelvic inlet makes with the horizontal is greater than the normal, and the angle to the vertical will be correspondingly reduced. In a contracted pelvis the promontory of the sacrum will be nearer the plate than the normal, and be more easily defined.

#### Method of Measuring.

In a normal pelvic bone, which is designated the "standard pelvis," the various diameters, both external and internal, are accurately measured. When this bone is radiographed definite points can be marked on the plate; the distance between these points will bear a definite ratio to that between the corresponding points measured on the pelvis. This radiograph is taken as the "standard plate." By radiographing the patient in the same position as the "standard pelvis," an accurate comparison of the patient's plate with the "standard plate" will be obtained, and therefore of the patient's pelvis with the "standard" or normal pelvis; from it the internal measurements can be mathematically worked out. When compared with the direct measurements they are fairly accurate. To work out mathematically, for example, the transverse diameter of the pelvic inlet the length of the transverse diameter of the pelvic radiograph of the patient is multiplied by the transverse diameter of the standard pelvis, and divided by the transverse diameter of the standard plate. In the same way the antero-posterior diameter of the inlet, or the transverse diameter of the outlet, can be worked out. I have not mentioned the oblique diameters, but if the true conjugate is diminished the oblique will also necessarily be reduced in proportion.

#### The Foetus.

It is possible to obtain the x-ray shadow of the foetus in utero, and this is a great clinical and medico-legal advantage in cases in which there is doubt as to the presence of pregnancy or the existence of an abnormality. The earliest period at which I have been able to recognize the foetus has been during the fourth month, and only that part of the foetus over the inlet is demonstrable. There are several factors which militate against the diagnosis of pregnancy in the early months—namely, the thickness of the maternal tissues, the hypercongestion of the uterine walls, the amniotic fluid, and the slight density of the foetal bones. It is necessary to take the x-ray plate in the earlier stages, if pelvic measurements are required, for in the later stages, it will be readily understood, the outlines of the pelvis may be more or less obliterated by the presenting part. An accurate comparison between the foetal skull and the pelvic inlet can be obtained if the photograph be taken when the head is about to engage in the pelvis.

While it is possible to measure the diameter of the head which lies parallel to the transverse diameter of the pelvis, it is not so with the diameter which enters the true conjugate. Therefore dependence must be placed on comparison rather than measurement.

Even on finding the relations of the foetal head to the mother's pelvis satisfactory we must take into account the inability to judge the exact amount of mobility existing between the bones of the foetal skull, which, if soft, during the efforts of labour would mould themselves to the pelvis, but if densely ossified would be incapable of reduction in size.

The overlapping of the skull bones can be easily recognized during the first stages of labour. If engagement is impossible there is also distinctly seen overlapping by the foetal skull of the pelvic inlet, especially in the region of the symphysis pubis. The recognition of this inability on the

part of the foetus to navigate the passages successfully would spare, by a timely Caesarean section, many a mother a difficult labour with extensive damage, and save the life of many a child.

#### Effects on the Mother and Foetus.

While it is recognized that large doses of the x rays will produce an artificial menopause, the short exposure which is required for obstetrical diagnosis has no deleterious effect on the mother, and does not even produce a temporary sterility. In none of my cases when the x-ray exposure has occurred during pregnancy has intrauterine death been produced, nor has any physical or mental maldevelopment shown in the newborn child.

#### Conclusion.

In conclusion, I would like to emphasize the following points:

1. The necessity of a "standard" plate for pelvic measurements.
2. The patient must be radiographed in the same position as the "standard" pelvis, having the same point of focus, the x-ray tube at the same angle and the same distance from the sensitive plate.
3. The accuracy of diagnosis in showing to advantage the variety of pelvic contraction, and the ease with which the various pelvic diameters can be worked out.
4. The minimum amount of discomfort to the patient compared to other methods of pelvimetry.
5. By the collaboration of the roentgenologist and the obstetrician there exists a valuable means of conserving maternal and foetal life.

To Dr. Beath, roentgenologist to the Royal Victoria Hospital, Belfast, and his assistant, Mr. Leeman, I express my gratitude for their assistance in taking the photographs shown to the Section.

#### DISCUSSION.

The PRESIDENT said that the Section was very much indebted to Dr. MacKenzie. The photographs he had shown were very striking, and there was undoubtedly a great future for this method. What they really wanted was a method whereby they could diagnose the small degrees of pelvic contraction, not the larger ones. He was rather doubtful whether this method would reveal these minor contractions. Another objection he had to make was the great difficulty that he met with in getting such excellent pictures taken.

Dr. JOHN CAMPBELL (Belfast) thought that due attention had not been paid to this important aspect of obstetrics. He personally had obtained much valuable information from this method. Accurate measurement of very minor degrees of pelvic deformity could be obtained. The attention of the profession should be directed to this method, as it gave information which could not be obtained by other means.

Dr. LOUISA MARTINDALE (London) drew the attention of the meeting to some beautiful photographs of foetuses which had recently been taken in Germany.

Dr. HENDRY (Glasgow) expressed his admiration for the plates. His only objection to the method was that it did not allow of manipulation of the head to see what difference flexion, etc., might make to the prospects of normal delivery. Such information could be obtained by Professor Munro Kerr's method of examination.

Mr. LANE ROBERTS (London) asked whether any movements of the sacro-iliac joints had been observed during the taking of these skiagrams.

Dr. MACKENZIE, in his reply, said that it was entirely due to the encouragement he had received from Dr. John Campbell that he had persevered with the method up to the point of perfection they had so far obtained. The most minor degrees of contraction—to one-twelfth of an inch—could be recognized by this method. He had been able to identify a four months' foetus in utero, a point of valuable medico-legal significance. The great advantage offered by his method was that it would be possible at an early stage of pregnancy to discover whether the pelvis was normal or not. He had not had any experience in these photographs of movements of the sacro-iliac joints.

Dr. COOK discussed the seasonal variations of the disease and said that the disease was liable to exacerbation during spring and autumn, the reason for this being Mr. PARSONS thought that heredity played part in some cases and cited instances. He also drew attention to the fact that the distribution of the disease occasionally followed the distribution of syphilis. He also mentioned the fact that the disease sometimes occurred in systemic diseases like lupus erythematosus and leprosy.

*Tests for Syphilis.* CARX MONAG gave a demonstration of the reaction and a flocculation test for syphilis. How the antigen was prepared from the heart and tubes showing flocculation with this and serum. He then showed the parts played by complement in the Wassermann reaction. Examples used in the Wassermann reaction. Examples of strong positive, weak positive, and negative

of the London Association of the Medical  
ederation was held at the Elizabeth Garrett  
Hospital on November 13th, with Miss M.

As a factor to be reckoned with in practice, its geographical position and the special value of the various springs, explaining suitability for internal and which for external and deprecated the habit of sending patients without confiding them to the care of a physician. Mineral waters of any potency could not be taken at any time and in any quantity, and the attempt on the part of the patient to treat ended disastrously. As to diet, in English medical practitioners had not the same advantages of being able to superintend the Continent. The Harrogate Medical Society had again attempted to solve the problem. The difficulty much with the hotel managers or with the patients' friends, who refused to be so simple diet. Patients came to Harrogate in many widely different complaints, as the spa, was equipped with facilities for all sorts of ur, heat, needle, electric, paraffin, wax, and baths among others, and also for special treatment as the Buns system for throat and nose affected. Plombaries treatment for colitis.

H. Moirais read a paper on the waters of Bath, since the previous speaker had dealt mainly the physical and physiological aspect of the important discoveries had been made in recent the composition of the waters of Bath by the Ramsay; and at the present time researching carried on at the Mineral Water Hospital result in increasing the knowledge of the

A paper on pitfalls of medico-legal practice was read by Sir John Coltate to the members of the Harveian Society at the Town Hall, Paddington, on November 15th. Members of the Medico-Legal Society attended and took

part in the discussion which ensued. Sir John Collicle advised medical men in medico-legal cases to conduct examinations in their own consulting rooms—the effect on the examinee was enormous. A solicitor's office was the last place for such an examination. He himself had refused to examine a case at a solicitor's office, and the point was taken to the Court of Appeal, who decided in his favour. He further advised medical men never to be in a hurry in examining a medico-legal case. A thorough examination should be made, and if the examinee asked, "What do you think?" the doctor should reply, "What I think I will tell the insurance company," otherwise he might be providing a rod in pickle for himself in the witness-box. Next the speaker advised doctors to "take notes at the time and preserve them." If a doctor as much as referred to notes when giving evidence he might be asked, "Were those notes taken at the time?" If they were not he would be told to put the notes in his pocket and to give evidence to the best of his memory. Sir John Collicle said he himself had been frequently challenged upon typewritten notes which he had said were typewritten immediately after an examination and in some cases he had been allowed to refer to them. The only safe course, however, was to take notes at the time and have them in the witness-box. Again, in writing a report a doctor must not allow sympathy to have any say in the matter whatever. They were all afraid of the law of libel, but if a doctor was to do his duty in making

## DEFORMITIES OF THE SYPHILITIC NOSE.

BY

H. D. GILLIES, C.B.E., F.R.C.S.

THERE are three classes of deformities in the syphilitic nose, according to the extent of destruction caused by the disease:

1. A small amount of cartilaginous septum with mucous membrane may be lost.
2. The common type—loss of the bony cartilaginous bridge, combined with great destruction of the mucous membrane.
3. The same type of destruction as in Class 2, but with the additional destruction of some or all of the external skin.

The repair of the deformities varies according to the amount of destruction; in other words, the diagnosis of

there is always a peculiar look about the nose which, even to the untrained eye, is strongly reminiscent of the disease from which the patient originally suffered; whereas, if the mucous membrane be regrafted, in one operation the whole character of the nose will be changed, and the syphilitic appearance of the patient entirely removed.

As will be described presently, it is not possible to graft mucous membrane, as such; consequently, thin Thiersch-grafted skin is made to take its place; but when this part of the operation has been successfully performed the nose takes on the appearance of a simple depressed fracture, which can be readily remedied by the implantation of cartilaginous support. This provision of a mucous membrane lining in a syphilitic nose is so important that the methods of introducing the skin graft should be described.

If the photograph (Fig. 6) be examined it will be seen that there is entire destruction of the whole osteo-cartilaginous support, and, in addition, an extreme retraction of the tip and alae of the nose, without any concurrent loss of the external skin; in fact, the skin of the vestibule is intact—the destruction having stopped short

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

Figs. 1 and 2 show the condition before operation; Fig. 3 the result of the first operation—intranasal skin graft; and Figs. 4 and 5 the appearance of the patient (full face and profile) after the second operation—cartilage graft.

the deformity rests on the accurate estimation of the amount and character of the tissue lost.

## CLASS 1.

In this class (which is not common) the deformity resembles that so often seen following a septal abscess or a too vigorous submucous resection. The deformity is confined to the bridge of the nose and is due to loss of the cartilaginous support. All that is necessary in this case is to supply by implantation a piece of cartilage of the shape and support originally given to the nose by the septum. The method of operating has already been described in the *Proceedings of the Royal Society of Medicine* of this year.

## CLASS 2.

The common or typical syphilitic nose is to be severely distinguished from the above type in that there is a large loss of mucous membrane lining the nose in addition to the osteo-cartilaginous support. Consequently, in accordance with the principles which have already been enunciated, no satisfactory result can be obtained without supplying a substitute for the mucous membrane in addition to supplying a substitute for the missing bridge of the nose.

Many surgeons have attempted to repair this class of syphilitic deformity by means of cartilage or bone implantations, or even paraffin injections, without in the first place realizing the loss of mucous membrane, or, in the second place, of attempting to supply this element; and although in some cases an improvement has occurred,

at the more resistant skin element—consequently you will find this skin of the vestibule firmly adherent to the margin of the altered pyriform opening.

In order to bring the tip of the nose and the alae down into their respective normal positions it is necessary to divide freely their attachments to underlying bones. If the skin be undercut in this manner it is possible to pull the nose out like a concertina, and on examining the nose in its now normal position a very large raw area, uncovered by any epithelium, will be discovered facing the nasal cavity. It is this raw area that should be skin-grafted.

## Method of Operation.

The case is first referred to a competent dental surgeon, who makes a small removable cap splint for the upper teeth. To the centre of this splint an upright semi-flexible wire, with expanded ends, is attached; it should be of such a length that it will come to lie approximately under the raw area. The splint being already on the teeth, an incision is made in the upper buccal sulcus from one canine fossa to the other. The soft tissues are separated from the bone until the nasal cavity is reached and opened.

The incision is now carried up laterally until the alae are freed from their various vicious attachments to the remains of the pyriform opening. Still further the incision is carried up over the remains of the bony bridge to the root of the nose (care being taken not to injure the outside skin) and laterally to the region of the inner canthus on each side.

## TREATMENT OF GONOCOCCAL INFECTION BY DIATHERMY.\*

BY

E. P. CUMBERBATCH, B.M., B.Ch.Oxon., M.R.C.P.,  
MEDICAL OFFICER IN CHARGE OF THE ELECTRICAL DEPARTMENT, ST.  
BARTHOLOMEW'S HOSPITAL; PAST PRESIDENT OF THE SECTION OF  
ELECTRO-THERAPEUTICS OF THE ROYAL SOCIETY OF MEDICINE;

AND

C. A. ROBINSON, M.B., B.Ch.Cantab., D.M.R.E.Cantab.,  
MEDICAL OFFICER IN CHARGE OF THE ELECTRICAL DEPARTMENT, WEST  
MIDDLESEX HOSPITAL; CLINICAL ASSISTANT TO THE ELECTRICAL  
DEPARTMENT OF ST. BARTHOLOMEW'S HOSPITAL.

THE clinical investigation of the treatment of gonococcal infection by diathermy was commenced in the electrical department of St. Bartholomew's Hospital in 1913. An indication of the value of diathermy for this purpose was furnished by the results obtained in two cases of gonococcal arthritis. These cases had resisted long courses of treatment in the wards by other methods and were then sent to the electrical department. Diathermy was applied to the joints, and the results were so good that other cases of the disease were subjected to the same treatment. Equally encouraging results were obtained. It was therefore decided to investigate the effect of diathermy on gonococcal infection of other parts. Cases of epididymitis and orchitis were treated, and, afterwards, cases of endocervicitis and urethritis in the female and prostatitis in the male. Up to the present we have treated 67 cases. The purpose of this paper is to describe the results which we have obtained and to indicate our methods of procedure. The latter have been varied from time to time, and it is likely that further improvement will be suggested with gain of experience.

The reasons for the selection of diathermy for the treatment of infection by the gonococcus are the following. The organism mentioned can be destroyed at a temperature which is not high enough to damage the living tissues. In diathermy we possess a means of raising the temperature of the tissues *en masse*, whereas other methods of applying heat raise the temperature of the superficial parts only. The clinical results and bacteriological tests have abundantly justified the use of diathermy for the purpose mentioned, and the reasons just given furnish a rational explanation of the mode of action of the new method of treatment. In almost all our cases of gonococcal arthritis we were able, within a comparatively short period of time, to abolish the pain, reduce the swelling, and increase the range of movement; crippled joints were rendered useful, and patients who had been compelled to stay in bed before the treatment were able to walk about with a considerable degree of comfort after a course of diathermy. Cases of gonococcal orchitis and epididymitis without exception quickly lost their pain and swelling after diathermy, even if the symptoms were severe.

Convincing proof of the therapeutic power of diathermy in gonococcal infection was furnished by the disappearance of pain and swelling from joints or scrotum after the application of the treatment to the *site of the original infection*. Cases of gonococcal arthritis were freed from pain after application of diathermy to the urethra and prostate, or urethra and cervix, without the inclusion of the joints in the treatment. We have also had cases in which the application of diathermy to the joints did not procure much relief until the parts originally infected were included in the treatment.

We have applied diathermy to the urethra and cervix uteri in the female in cases in which these parts alone were infected. Such applications were followed by disappearance of the gonococci and cessation or diminution of the discharge. The failure to find gonococci in a discharge does not prove that these organisms are not present in the parts from which the discharge originates. But if repeated attempts to find them are unsuccessful and a

mucous discharge alone remains—not excessive in amount, and without bacteria—it may reasonably be concluded that the treatment has been effective. Further proof of the efficiency of diathermy in the treatment of infection of the cervix and urethra is afforded by the fact above mentioned—namely, the subsidence of arthritis after application of diathermy, not to the joints but to the parts originally infected.

The treatment of gonococcal infection of certain regions, whether by irrigation, external applications, or vaccines, is unsatisfactory. This is the case especially with the joints, the cervix uteri and urethra in the female and the prostate in the male. Almost all the cases which we have treated had been previously subjected to other forms of treatment, and we were able by means of diathermy to procure success where other methods had failed.

### *Sensitivity of the Gonococcus to Heat.*

Gonococci are destroyed if the temperature of the medium on which they grow is raised a few degrees above normal. Cultures of these organisms do not survive if they are left overnight in an incubator and the temperature of the latter has risen to 102°. Some experiments were made by Santos to ascertain the temperature and the length of exposure sufficient to kill cultures of gonococci. He found that exposures to 43° C. for seventy-six minutes, to 44° C. for fifty-four minutes, and to 45° C. for thirty-seven minutes were required. Laqueur injected emulsions containing living gonococci into the joints of dogs, and found that the joints which were exposed to diathermy contained a sterile fluid while those which were not exposed contained living organisms.

Cases have been noted of the influence of pyrexia due to other causes on coexisting gonorrhoea. One case was that of a man who had suffered for a long time from gonorrhoea which had resisted treatment. When residing in West Africa he acquired blackwater fever; on his recovery from the later the gonorrhoea had disappeared and did not return.

In addition to its direct action on the gonococci diathermy produces certain effects in the tissues which are prejudicial to the existence of the organisms. The increase of the supply of blood to the heated tissues probably has some therapeutic effect. The application of diathermy to mucous membranes causes an increased exudation of lymph and secretion of mucus. The drainage of the infected parts is thereby aided and it is possible that the heated lymph and mucus exert a germicidal action.

### *Treatment of Gonococcal Arthritis by Diathermy.*

Our earliest experience of the action of diathermy on infection by the gonococcus was obtained in cases of arthritis. We shall therefore describe our experience in the treatment of this disease first.

The space at our disposal will not allow a detailed description of our methods of applying diathermy to different joints. It is necessary that the current should be directed *transversely* through the joints rather than longitudinally. The applications should last not less than twenty minutes each, and they should be repeated not less frequently than twice weekly. Longer and more frequent applications would probably procure quicker results.

In our first seven cases diathermy was applied to the joints only and the average number of applications was nine. Relief of pain was procured, however, by a considerably smaller number than nine, and the patients usually obtained some relief after the first treatment. Some of the subsequent cases did not obtain relief until the diathermy was applied, in addition, to the original site of the infection. It is now our custom, in all cases of arthritis, to apply diathermy to the urethra and prostate or urethra and cervix uteri as well as to the joints. Quicker and better results are obtained when this is done. In two cases, however, we were able to procure complete relief of pain by applying diathermy to the parts first infected without including the joints.

Up to the present time we have completed the treatment of 25 cases of gonococcal arthritis: 13 of these were in

\* This paper is an abstract of a monograph which contains details of cases and particulars of experiments and methods. The monograph will be published as soon as possible.

## 55

the first application, and after the third there are no symptoms or signs of abnormality save slight thickening of the epidiidymis without tenderness on pressure. We have never found it necessary to give more than four applications and in the majority of cases three were sufficient.

It is usually stated that pain and tenderness will subside from the testis and epididymis when the urethra has been successfully treated by the customary methods. We have had cases, however, in which the urethral discharge had disappeared after treatment, leaving, however, pain, tenderness, and swelling of the epididymis and testis, which would not subside until diathermy was applied. We have also had cases in which diathermy produced the results above described even though a discharge containing gonococci was still present.

In cases which respond successfully to methods of treatment other than diathermy the pain and tenderness do not subside before six weeks have elapsed. With diathermy, however, the period of treatment is a week or ten days, and the number of applications rarely exceeds three. This number will probably produce the same effect if given in less than a week, but in hospital practice we cannot as a rule treat such cases more frequently than twice weekly.

*Treatment of Gonococcal Urethritis (Female) and Endocervicitis.*

During our investigation of the action of diathermy on gonococcal arthritis in the female we found that some of the patients did not derive much relief until the regions first infected were subjected to the same treatment. This indicates that diathermy has some therapeutic action on the urethra and cervix when infected by the gonococcus. In order to ascertain the extent of this action we applied diathermy to cases of gonorrhoea in the female in which there was no complicating arthritis and noted the effect on the gonococci and the discharge.

For the application of diathermy to the urethra and cervix we have conducted experiments and as a result have revised methods the usefulness of which we have investigated. For reasons of limitation of space we are unable to describe these or give details of technique. We have used a bougie electrode for the urethra and have found that the patients were sufficiently sensitive to heat in this part to prevent the application of a current which would damage the mucous membrane. This is not the case with the cervix. To apply a safe degree of diathermy without pain to the patient. To apply a safe degree of diathermy currents and familiarity with their clinical use is necessary, but, briefly described, our procedure is to note the strength of the current previously used for the urethra and to apply an amount to the cervix proportional to the smaller extent of surface in contact with the bougie when it is in the cervix. Probably an easier method would be to use electrodes fitted with thermometers. At present we are occupied in the construction of such electrodes.

Up to the present we have treated 16 patients who, suffering from vaginal discharge, sought treatment at the special centre. Gonococci were found in 14, either in the urethra or cervix or in both parts. These patients had been subjected to treatment at the centre by the customary methods, and as the discharge and the gonococci did not disappear it was decided to try the effect of diathermy. Both the urethra and the cervix were treated and the average number of applications was four to each part. At the end of the treatment and at later intervals each case was examined bacteriologically. With one exception, no gonococci were discovered, nor were they found at later periods. The length of time for which the patients were under observation depended on the ability with which they obeyed their instructions to report for examination. It varied from two months to one year.

The failure to find gonococci is insufficient evidence of freedom from infection by these organisms. Four of our cases, however, stated that they were free from discharge and no discharge was visible on examination. Two of these cases did not report for further examination. The other

Of the 25 cases 19 were in out-patients who came from a special centre for the treatment of venereal diseases, the others were in in-patients at St. Bartholomew's or the Middlesex Hospital. Three of the cases had been admitted before admission to hospital. The ages of the patients varied from 16 to 56. In 7 cases one joint only was affected, two joints were involved in 8 cases, three in 4 cases, four joints in 2 cases, while in the remaining 4 cases more than four joints were affected. With two exceptions the cases derived the greatest benefit from diathermy; pain was abolished, swelling was reduced, and the range of movement was increased. Patients who had required the use of crutches or sticks were capable of resuming their work. Others who had been unable to follow their occupation owing to pain in their limbs were able to resume their work, and were bed-ridden patients were able to get up and walk about. In the cases in which the infection had persisted for long periods and caused thickening of the synovial membrane and ligaments and capsule of the joints and destruction of the articular cartilages slight swelling of the joints remained together with some limitation of movement. These cases were, however, freed from pain and tenderness and the joints could be used without discomfort, that further treatment by other physical methods produced additional usefulness of the limbs. If the three joints may follow long-continued gonococcal arthritis be remembered (Osler described this condition as "in some" respects one of the most damaging, disabling and serious of all the complications of gonorrhoea " ") it may be claimed that the results of treatment by diathermy are far superior to those obtained by other methods. In the two cases in which the results were less satisfactory we were unable to complete the treatment. One of these was that of a girl, aged 16, an in-patient, who suffered severe pains in many joints. The fluid from the application of diathermy to the joints procured some relief—she no longer screamed with pain when lifted from the couch, on cultivation, grew one colony of gonococci. The application of diathermy to the joints procured some relief to the pain in his joints so that he had fair nights and his general condition improved. The discharge from his urethra did not entirely disappear, but he no longer passed clots of pus with pain and strangury, as had been the case before the treatment was applied.

## Reviews.

### A SYSTEM OF SURGERY.

THE appearance of the second edition of the *System of Surgery*<sup>1</sup> by CHOYCE and BEATTIE was postponed owing to the war, but any disappointment caused by the delay is more than compensated by the care with which the volume has been prepared. Though the text is the work of various authors a high level of uniformity has been attained. All the articles are practical and well illustrated. There are some 150 new illustrations, including 50 new plates. All the previous contributors have not only revised, but in many cases rewritten, their articles, and the aid of several new writers has been enlisted. Thus the article on orthopaedic surgery has been rewritten by Mr. W. H. Trethowan, that on fractures by Mr. Hey Groves, that on x-ray diagnosis by Mr. Magnus Redding, that on tetanus by Colonel West, that on the ear, nose, and throat by Mr. Norman Patterson, and that on syphilis by Colonel Harrison. The recent advances in war surgery on vascular injuries, haemorrhage, fractures, infective wounds, and gangrene are included in the text, and gunshot wounds are only noticed when they have a bearing on civil surgery.

Volume I deals with: Surgical bacteriology (Dreyer), its therapeutic application (Eyre), inflammation (Beattie and Maynard Smith), suppuration (Lenthal Cheatle), ulceration (Pannett), gangrene (Nitch), wounds (Choyce), burns and scalds (Woodward), trauma (Russell Howard), toxæmia, septicæmia, pyæmia (Martin), tumours (Raymond Johnson), blood and cerebro-spinal fluid (Beattie), x-ray diagnosis (Redding); anaesthesia (Bloomfield, Gwynne Williams, and McGavin); tuberculosis (Beattie); syphilis (Harrison); venereal disease other than syphilis (Leedham-Green); tropical diseases (Daniels); glanders (Rock Carling); actinomycosis (Choyce); tetanus (West); hydrophobia (Calmotte); anthrax (Philip Turner); diseases caused by animal parasites (Madden).

It is difficult to particularize in a work of such all-round excellence, but the articles which attract particular attention are those on gangrene, which is well classified and the treatment up to date; on tumours, which is remarkable for its good series of illustrations; and on x-ray diagnosis.

Volume II deals with: The breast (Sampson Handley); the spleen (Gordon Watson); malformations of the face, lip, and palate (Nitch); the tongue (Clayton Greene); salivary glands and floor of mouth (Back); the oesophagus (Rigby); stomach and duodenum (Sherren); intestines (Miles); appendix and peritonæum (Percy Sargent); hernia (McGavin); rectum and anal canal (Clogg); liver, gall bladder, and pancreas (Grey Turner); urinary tract (Thomson-Walker); genital tract (Russell Howard).

Diseases of the breast are very thoroughly dealt with by Mr. Sampson Handley, who includes an account of the spread of carcinoma by permeation, and of Paget's disease of the nipple, and a full discussion of operative methods and of the value of x rays and radium. He states that local recurrence is rare and considers the means which should be used to prevent it. Mr. Clayton Greene expresses a general pessimism on the subject of cancer of the tongue. He considers the ideal is to remove the tongue and glands at the same time, but if the two-stage operation is to be performed it is better to remove the glands first. He recommends the use of diathermy and removing the tongue right down to the hyoid, and quotes Quick's work on the treatment by radium. The arguments for and against the operation of choice on cleft palate and hare-lip are clearly put forth and well balanced. Mr. Nitch's conclusion is that Lagenbeck's operation performed between the ages of 18 months and 2 years gives the best results in the majority of cases, and that coexisting hare-lip should be operated upon at the age of 3 months. Mr. Sherren's article on gastric ulcer is specially clear and concise. Small chronic ulcers are treated by gastro-enterostomy and in "free" ulcers

the cautery may be used in addition, but where the ulcer is indurated, adherent, or suspicious of carcinoma partial gastrectomy should be carried out. Mr. Clogg's article on rectum and anal canal is a valuable contribution, in which the operative measures on carcinoma of the rectum are summarized. Mr. Grey Turner in his article on gall stones holds the balance between cholecystostomy and cholecystectomy, and enumerates the several conditions under which each may be employed.

Volume III deals with the following subjects: Female genital tract (Victor Bonney); cardio-vascular system (Rock Carling); lymphatic system (Dobson); the neck (Edmunds); nose and accessory sinuses (Barwell); pharynx, nasopharynx, larynx, and ear (Patterson); direct examination of the lower air passages (StClair Thomson); lungs and pleura (Morriston Davies); nerves (Sherren); scalp, skull, brain, spine, and spinal cord (Trotter); jaw (Fitzwilliams); skin and subcutaneous tissues (Legg); muscles, fasciae, and tendons (Rock Carling); bursae (Telford); diseases of bones and joints (Choyce); fractures (Hey Groves); orthopaedic surgery (Trethowan). Mr. Trotter's articles on the brain and spinal cord are a pleasure to read, and constitute a fine translation of the physiological and anatomical principles of the central nervous system into practical treatment. Mr. Trethowan has a vigorous article on orthopaedic surgery, and though, judging from the amount of small print in the text, his space is cramped, his style is not. He ends with a note on manipulative surgery, with the motto "when in doubt move," as applied to joints. Mr. Hey Groves in his article on fractures lays special stress on the subject of treatment, and it is pleasing to see new and up-to-date illustrations of splints, and the *coup de grâce* given to those old ones which have been handed down in textbooks from time immemorial. Mr. Choyce is at his best on diseases of the bones and joints, and his clear concise rendering of this subject is a model of information to the inquiring student. The principles of plastic surgery are included in Mr. Legg's article on the skin and subcutaneous tissues.

The editors express a modest hope that this work "may be regarded as a satisfactory example of the teaching of British surgery." It is more than satisfactory, and as a standard textbook on the surgery of to-day it has few rivals and no superior.

### CLINICAL ELECTRO-CARDIOGRAPHY.

THE practice of electro-cardiography is becoming sufficiently common to justify a book of the character of Dr. WILLIUS's *Clinical Electrocardiography*.<sup>2</sup> In any case those who are more especially interested in heart disease find it essential to be able to understand the records obtained from the string galvanometer. The author has given us a book which, whatever its defects, will prove of considerable assistance to practitioners. A short concise description of the electro-cardiograph and the method of obtaining records is preceded by a brief account of the physiological considerations. The remainder deals with the various arrhythmias, their classification and recognition, and also with the prognostic significance of certain well defined deviations from the normal.

Dr. Willius has collected a large amount of valuable material dealing with this phase of electro-cardiography. He groups the deviations into those with T wave negativity, those with spread of the Q.R.S. complex, and those with a combination of the two. His figures indicate unhesitatingly that abnormal electro-cardiographs of this grade, other things being equal, carry with them a graver prognosis than when the electro-cardiograph is normal. He refers to 155 cases of angina and gives the electro-cardiographs of 46 cases. There is no specific deviation found to be characteristic of angina, but the average prognosis is graver when the electro-cardiograph is definitely abnormal.

Here and there the illustrative records are open to criticism. In fact in a few, such as Figs. 58, 76, and others, the interpretation is faulty. In some it is open to

<sup>1</sup> *System of Surgery*. In three Volumes. Edited by O. C. Choyce, C.M.G., C.B.E., B.Sc., M.D., F.R.C.S. Pathological Editor, J. Martin Beattie, M.A., M.D., C.M. Second edition. London and New York: Cassell and Co., Ltd. 1923. (Med. 8vo. Vol. I, pp. xxii + 1013; 245 figures, 77 plates. Vol. II, pp. xv + 1057; 356 figures, 30 plates. Vol. III, pp. xv + 1176; 329 figures, 41 plates. 46 net the set.)

<sup>2</sup> *Clinical Electrocardiography*. By Dr. WILLIUS. Section on Clinical Medicine, Rochester, Minnesota, and The Minnesota. London and Philadelphia. 1922. (Med. 8vo, pp. 188; 185 figures. 2ss. net.)

perfectly prepared to call together my Consultative Council and wrote them a very long letter in reply to one which they sent me this morning.

Lieut.-Colonel Pownall inquired whether the Minister would arrange that the Friendly Societies should be represented, and Sir Kingsley Wood wished to know whether it was open to any insured person to go before this Court of Inquiry and give evidence as to the character of the panel service, and to urge Sir W. Joynton-Hicks: "There are something like fourteen million insured persons, and if they all claim the right to appear before the Court of Inquiry and state their views."

Lieut.-Colonel Nall asked whether, in the final consideration of this question, the chief interest to be considered would be that of the insured persons. Sir W. Joynton-Hicks: "Certainly. The object I have had in all these negotiations has been to get an adequate and proper medical service. Mr. Davies asked when the Minister would be able to state the personnel of the Court of Inquiry. Sir W. Joynton-Hicks: "I have already dictated letters to three gentlemen whom I have asked to act, and I believe that those letters will be here to be signed by me within the next few minutes."

Sir Kingsley Wood asked whether the Minister could announce the terms of the inquiry—the form of the reference which was to be put before the Court. Sir W. Joynton-Hicks: "No, sir, but it will be a very simple one. I have not drafted it yet, but I may say, without binding myself to the exact terms, that it will simply be to ask the Court of Inquiry to ascertain what is the correct figure to be paid to the doctors for the medical service they render."

Sir J. Butcher: "Will it be open to the representatives of the panel doctors, as well as to the representatives of the Approved Societies, to appear before the Court of Inquiry?" Sir W. Joynton-Hicks: "Yes, sir; both parties."

# Workmen's Compensation Bill.

On the report stage of this measure, on November 13th, Mr. G. Spencer moved for the addition of a clause to apply the principal Act to miners' pneumoconiosis or its sequelae. The Under Secretary for the Home Department (Mr. Godfrey Locker-Lampson) pointed out that the effect of the amendment would be to add the disease to the permanent schedule of the original Act, and would allow of no modification of it by order. This would be true also of the sequelae. In the recently published second report of the Nystagmus Committee it was made clear that the definition of Nystagmus was too wide. The amendment was rejected by 185 to 102.

Another new clause was moved by Mr. Lowth to include in the schedule "any disease or affliction of the eye attributable to, or aggravated by, the employment." The Solicitor-General said that if a case could be made out for the inclusion of a particular disease it would be included, but the amendment was too wide. It was rejected by 187 votes to 176.

On November 14th the Solicitor-General moved to insert, in place of a subsection passed in Committee, a new one to lay down that the power of the Registrar of a county court, under paragraph 15 of the first schedule of the principal Act, to refer a matter to a medical referee, might be exercised on the application of one of the parties, as well as on the application of both, subject, however, to appeal to the judge. The new subsection further laid down that where the application was made by only one of the parties, the Registrar or, on appeal, the judge, if he were of opinion that, owing to the exceptional difficulty of the case or for any other sufficient reason, the matter ought to be settled by arbitration, should refuse to allow the reference. If either the employer or the workman thought the case was one that might properly be decided by a medical referee, power was given for application to the judge to order such reference, subject to the condition that if it was a case of neurasthenia or hysterics, where there was a conflict of medical opinion, the judge might say: "I had better hear the case myself, and do the best I can." It had been suggested as an alternative that there should be reference to three medical men, but that would mean, in a case of a difference of opinion, two would be on one side and one on the other, and be no better than having the opinion of one. Moreover, such a method was more expensive. A third alternative would be to leave the decision with the medical referee, subject to an appeal to the judge; but many people would object to an appeal.

Mr. T. Shaw, on behalf of the Labour party, said they were strongly of opinion that in highly technical cases there should be a Board of Referees with at least three medical men upon it. The Labour party thought that there would be better than having the evidence of medical men on each side, presented as far as possible to represent the view of the party for whom the particular medical men were giving evidence.

Mr. Greaves-Lord held that the best tribunal would be to have a court in which a medical assessor—in other words, where the medical referee said that the man was still suffering from the

## Pensions and Allowances.

In reply to various questions Captain Craig has given the following information:

The total number of persons in receipt of pensions from the Ministry of Pensions in September 1923, was 2,300,000, as compared with 2,638,000 a year previously. The details were as under:

September, 1923.	September, 1922.	2,638,900	2,303,400
Officers and nurses	31,500	31,500	28,000
Officers' widows	6,500	6,500	5,600
Officers' dependants	8,700	8,700	8,000
Children of officers' widows	783,000	783,000	671,000
Men	157,500	157,500	151,000
Men's widows	359,000	359,000	354,000
Men's dependants	940,000	940,000	735,000
Men's wives and children	343,000	343,000	335,000
Men's widows' children	...	...	...

Excluding the cost of administration, the total expenditure of the Ministry for the year ended March 31st, 1923, was approximately seven million sterling, as compared with an expenditure of seven million sterling for the present financial year, a decrease of 8 per cent. The cost of administration (including that of medical services) would, it was expected, have fallen from £4,241,600 for the year ended March 31st, 1923, to £3,598,000, for the current year, a decrease of over £640,000, or nearly 16 per cent.

It was not the case that men admitted to be suffering from disabilities aggravated by war service had, as a class, been precluded from receiving medical treatment with allowances from the Ministry of Pensions. All that had been done by the Institute of the Ministry in regard to minor disabilities (of less than 20 per cent.) as far as possible into harmony with the existing practice in regard to major disabilities. No amending warrant was necessary for the purpose. If in any case a few more lessons than twenty-five were necessary in his reading for pensioners considered in the war, the Minister would always sympathetically consider it.

**Mental Treatment Bill.**—One of the misfortunes of the dissolution, involving as it has the curtailment of the autumn session, is that the Mental Treatment Bill, introduced in the House of Lords on behalf of the Ministry of Health, and passed through all its stages in that Chamber, reached only the second reading stage in the House of Commons. As bills cannot be carried over from one Parliament to another the measure is now defunct, and it remains for a new start to be made.

**Doctors and Midwives' Fees.**—The Minister of Health has stated in reply to a question that he understood that the fees of midwives varied from 15s. to 30s. in a case in rural areas, and from one guinea to two guineas in urban areas. He had no information as to the charges made by doctors attending such cases in their private practice, but when a doctor was called in by a midwife under the Act of 1918, he received a fee of two guineas from the local supervising authority. The services rendered for this fee were specified in a circular issued by his department.

question. On the whole, however, the illustrations are a helpful and valuable adjunct to the text, and the bibliography should prove most useful.

#### APPARATUS FOR THE IMPOTENT.

DR. GABRIEL BIDOU is a civil engineer who has devised and manufactured and patented various mechanical devices for the treatment of deformity, and others to enable the disabled to employ to the best advantage such powers as may remain to them. We have already noticed two small books by Dr. Bidou on instrumental orthopaedics (1919) and on artificial muscular action (1921). His new book<sup>3</sup> is more pretentious, judging from the numerous illustrations. M. Bidou's appliances are ingenious, well designed, and well made, and the descriptions of them and of the principles on which they are devised should be useful to surgeons who wish to learn something of orthopaedic mechanism. As in his previous works, Dr. Bidou places great trust in so-called artificial muscles—that is to say, in springs. It is scarcely necessary to reaffirm the objection that springs cannot take the place of muscles except in so far as they antagonize existing muscles and act when the latter relax. Besides the apparatus referred to, Dr. Bidou manufactures artificial arms and legs (patented) and machines for mechano-therapeutics and correction of deformity.

Dr. Babinski recommends this work in a short preface, and refers to the good results which have followed the application of Dr. Bidou's instruments to his patients in the Hôpital de la Pitié in Paris.

#### THE PHYSICAL CHEMISTRY OF THE CELL.

THE fifth edition of Professor HÖBER's treatise on the physical chemistry of cells and tissues<sup>1</sup> marks the ever deeper penetration of this branch of natural science into the fundamental problems of physiology. When the book first appeared chemists and physicists were only just mobilizing to the attack on the nature of the colloidal state and its peculiar energy relationships, the theory of electrolytic dissociation had but recently come into general currency, and the whole question of the energetics of chemical reactions was only slowly taking shape under the formidable title of thermodynamics. These deep movements of physical science had barely touched the fringes of physiological thought, yet there were those—and the author must be accounted among the first—who saw that these indeed were the lines of inquiry which were to lead to the intimate investigation of the living cell. To-day we are learning to look upon the cell not as a structure having localized affinities for certain dyes, but rather as a colloido-crystalloidal complex in a continuous state of disequilibrium in which the phenomena of assimilation, growth, movement, reproduction, and irritability are but the expressions of the physico-chemical reactions of this amazing complex. An explanation of the action of minute amounts of drugs, of hormones, and of enzymes, must be sought in the same field, and already the pathologist is turning to physico-chemical methods in the study of the disordered functions of the cell.

Such is the progress that Professor Höber is privileged to record in the pages of this new edition. He brings together the familiar with much scattered and unrecognized work, collecting them into a connected argument which gains much from the considered criticism of the author. He moves shrewdly and with a confidence which inspires courage in the reader through the wealth of material he has brought together. He seems to scent out the seeds of truth in this field so full of contradictions.

In the edition now before us the sequence of the discussion has been considerably modified, and it is obvious that new material has not merely been sewn into the old argument but has contributed to the remodelling of the whole. The phenomena of osmosis and permeability and their physio-

logical significance, whose discussion had previously been scattered through the book, have in this edition been collected and extended to comprise the whole of the second part of the volume. This chapter will be welcomed as a valuable contribution to the interpretation of the perplexing difficulties of the physical chemistry of permeability.

A second volume is promised, and while it is unfortunate that its scope is not indicated in the first half it will be awaited with interest. If there be a serious physiological library that does not already contain Professor Höber's book the omission may now very suitably be repaired.

#### CLINICAL PERIODONTIA (PYORRHOEA).

*Clinical Periodontia*,<sup>2</sup> by PAUL R. STILLMAN and JOHN OPPIE McCALL, instructors in periodontia in the Columbia University, New York, is "a study of the causes and pathology of periodontal disease and a consideration of its treatment." The authors' main thesis is that "traumatic occlusion" is the primary factor in periodontal disease, or, as it is generally called, "pyorrhoea." We may say at once we do not think they have established their case. They define traumatic occlusion as "an abnormal occlusal stress which is capable of producing or has produced an injury to the periodontium." So far as we can gather it is most obvious in the crowded arches of "mouth-breathers," but the authors find it in practically every mouth. Should any tooth be found by digital examination to move, even slightly, on closure of the jaws, the presence of traumatic occlusion is held to be established. The loosening is attributed to injury to pericemental membrane and alveolar crest by impact in abnormal position of cusp against cusp, and the bacterial invasion is held to be secondary to the trauma. The remedy suggested lies primarily in orthodontic treatment or in grinding the cusps to remove abnormal contact. Secondary, but by no means unimportant, treatment lies in mouth hygiene and general treatment.

As we have said, we cannot follow the authors in their opinion as to the injury done by "traumatic occlusion"; the teeth are designed to take strain and stress in a large range of positions and directions, and periodontal disease (or "pyorrhoea") is as common in people whose articulation is within the limits of normal as in those with demonstrably abnormal articulation. None the less the book is worth the attention of all thoughtful dentists. The chapter on radiographic appearances contains an excellent study of the minutiae of pathological conditions revealed by the x rays; the microphotographs of early gum affections through the periodontal sulcus are perhaps unique, and none of the clinical appearances of "pyorrhoea" from the most to the least obvious has escaped the authors, except it be the hypertrophic bone conditions. The publishers claim that this book is the first serious attempt to deal with the subject of periodontoclasia (pyorrhoea alveolaris) in a really comprehensive way, and however this may be the book is a valuable addition to the study of "pyorrhoea alveolaris," or, as the authors prefer, "periodontoclasia."

#### PALAEOPATHOLOGY.

*The Antiquity of Disease*,<sup>4</sup> a volume in the University of Chicago Science Series, is attractively written and well got up. It is by Dr. Roy L. Moodie, Associate Professor of Anatomy in the University of Illinois and editor of the late Sir Marc Armand Ruffer's *Studies in the Palaeopathology of Egypt*, which was reviewed in our columns at the time (BRITISH MEDICAL JOURNAL, 1921, ii, 991). Palaeopathology deals with the evidences of disease and injury in animals and plants before the records of medical history—namely, up to the time of Hippocrates. The small volume before us is mainly devoted to the vertebrata in this connexion. A brief sketch, starting from Esper of Erlangen in 1774, is given of the history of the

<sup>1</sup> *Nouvelle Méthode d'Appareillage des Impotents*. Par Dr. Gabriel Bidou, Membre de la Société des Ingénieurs civils de France. Préface de J. Babinski, Membre de l'Académie de Médecine. Paris: Les Presses Universitaires de France, 1922. (Roy. 8vo, pp. 311; 153 figures. Fr. 25.)

<sup>2</sup> *Physikalische Chemie der Zelle und der Gewebe*. Von Dr. med. Rudolf Höber. Fünfte Auflage, I Hälfte. Leipzig: Wilhelm Engelmann, 1922. (Roy. 8vo, pp. xv+544; 81 figures.)

<sup>3</sup> *A Textbook of Clinical Periodontia*. By Paul R. Stillman, D.D.S., and John Oppie McCall, A.B., D.D.S. New York: The Macmillan Company, 1922. (Demy 8vo, pp. 240; 73 figures. 15s. net.)

<sup>4</sup> *The Antiquity of Disease*. By Roy L. Moodie, Associate Professor of Anatomy in the University of Illinois. Chicago, Illinois: The University of Chicago Press, 1923. (Cr. 8vo, pp. xiv+143; frontispiece and 36 figures. 1.50 dols., post paid 1.60 dols.)

**Feveral Disease.**—Captain A. Evans asked, on November 16th, whether Clause 16 of the Trevelthan report, dealing with the expenditure of money for reducing venereal disease, had yet been considered by the Government; whether the question of Government financial assistance in the work had yet been decided; and whether in view of the fact that the Society for the Prevention of Venereal Diseases had both unconditionally accepted the Trevelthan report, and had met in the recommendations, he could suggest the maximum grant which was to be made by the Government to be divided in an equitable proportion between the two organizations. The Minister of Health replied that the recommendations in the report were now under the consideration of the Government. He was not yet in a position to say how any Government grant for the purpose mentioned had been allocated.

**Tuberculosis Order, 1917.**—The Minister of Health has received representations from local authorities urging that the tuberculosis order of 1917, which was suspended during the war, should be put into operation. The cost, however, was estimated at £50,000 from the Exchequer, and about twice that sum from local authorities. In the present financial stringency the Ministry would not feel justified in reviving the order in view of the small number of local authorities who had expressed their wish for its re-imposition.

**Glycerinated Gail Lymph.**—The Minister of Health stated that in view of the fact that there was no difficulty in obtaining from reputable firms supplies of glycerinated calf lymph of reliable quality, he did not think it necessary to accept the suggestion that a supply of the Government lymph should be made available to private medical practitioners. It would involve a large and costly extension of the present Government supply.

**Dried Milk.**—The new regulations as to dried milk make provision for a minimum fat content, and for suitable labelling, including the use of the words "Linf for babies," in the case of skim milk. It was necessary to allow a period of several months' manufacture to comply with the regulations in order to enable the position of the product to be made, and to put the milk into circulation in retail shops. The question of making regulations affecting other milk products was being considered by the Minister of Agriculture.

**Insurance in Brief.**—The figures at present available show a lower expenditure on sickness and disablement benefits from the National Health Insurance Fund in the first three quarters of the present year than in the corresponding period of 1922; the total expenditure on these benefits is within the actuarial estimate.

## PERSONAL RELATIONS BETWEEN MEDICINE AND LITERATURE.

LECTURE BY MR. EDWARD GOSSE BEFORE THE ROYAL COLLEGE OF PHYSICIANS.  
20th Mr. Edmund Gosse, C.B., LL.D., delivered the first David Lloyd Roberts Lecture, taking for his subject "Personal relations between medicine and literature." Sir Humphrey Rolleston presided over a distinguished gathering.

Mr. Gosse began with an appreciation of the man under whose bequest the lecture was founded. Roberts was not personally known to him, but he had had the advantage of consulting several eminent men who knew him well, in particular Dr. W. E. Robertson and Dr. Herbert Spencer. This old Manchester physician was born not later than 1835, so that he was at least 85 when he died in 1920. He coyly deprecated his years, and once, on complaining of his health to his lady patients and nursing, "I shall never see eighty," one sharp spiritist reproved him by saying, "You will never see eighty again." He was a self-made man, who retained a certain roughness of speech and oddity of manner which revealed an undisciplined individuality. Dr. Robertson said that it was the sight of a lifetime to see him canterize a carminative with a series of red-hot poker. This conveyed to the lecturer's wit, reminding him of Goethe: "Who would ever become a doctor if he could foresee the horrors which face him in that profession?" Another witness in a thump-nail sketched pictured Roberts in his old-fashioned brown, depicting out with great vivacity on both sides of the road, way so as to miss nothing in the stiffest of the boots, "solers' windows. He was a booklover, a collector in the best sense of the word, quick to perceive the value of an acquisition, eager to enrich his shelves, ready to exchange a moderately excellent specimen for one supremely good.

stuffed owls.

## The School of Salerno.

The famous school of Salerno in southern Italy was the nucleus of medical education in the early Middle Ages. In the dismal ninth century, when culture was perishing elsewhere, this little lamp shone at Salerno. The general tone of Europe was one of priest-ridden terror and abandonment to superstition and ignorance, but at Salerno they were eminently sane, preferring experience to conjecture, and centering their healthy interest in the body, not in vague researches into the nature of the soul. Sir Clifford Allbutt has noted that the professors of Salerno wrote in clear natural language, not the unlettered jargon of the schools. The Greek spirit and something of the Greek language lingered here. There flourished in the ninth century in France a physician called Floridus, probably the earliest physician-poet, who wrote an enormous constitution of

The lecturer was anxious to approach his theme in the spirit which Roberts would have approved. He failed to have less excuse than most men, for his communications with doctors and surgeons had been peculiarly agreeable. With Pope he could say, "There is no end to my kind treatment from the faculty." They are the most amiable companions and best friends, as well as the most learned men I know." In his own first youth it was his ambition to be a surgeon, and in fact he proceeded some little way in an imperfect preparation for an art for which he found himself constitutionally unfitted. That men of letters and medical men had for centuries betrayed an identity of sympathy is not to be found existing between the one mode of envisaging life and the other. It had been usual to group together medical men who had given literary form to their professional experiences and those who had written in poetry or prose on subjects independent of their professional work. He thought it important to keep these two classes as distinct as possible. It was plain that not everything printed in Latin or Greek, any more than in the vernacular, was literature. That almost incredible work, the *English Pharmacopoeia* of 1618, was no more literature than the prattle of popular almanacs. There was seldom any substitute for form among the compilers of such old works. But the greatest of ancient physicians were nevertheless conscious of the permanent value of literary ornament. Ambrose Pare noticed that Hippocrates wrote so that he might be understood by the women and girls who talked no language but Greek, and to achieve this end he wrote with attention to form which was the distinguishing mark of literature. It was not easy to say when these functions were distinctly combined in a published work. No criticism was necessary to show that the author of *Religio Medici* was a man of temporary Spedham, of whom it was said that he did communicate at divers times to the world the useful observations he made in the course of his practice? On the other hand, there need be no hesitation in placing out with their velvets and their dried crocodiles and their stuffed owls.

## The Two Professions.

one, his medical books to the other. He left his library to be divided between the John Rylands in Manchester and that College—the secular books to the

science of palaeopathology, the name introduced by the late Sir Marc Armand Ruffer.

Disease seems to have been entirely absent from the early and middle palaeozoic periods, and many groups or animals became extinct before its advent. Apart from injury the earliest form of pathological process was parasitism, preceded by mild forms of communism and commensalism; it was thus probably disease arose. The most ancient bacteria were non-pathogenic, and it appears probable that a wide distribution of bacterial disease is in geological time a comparatively recent phenomenon, going back a few million years, which in comparison with the scores, possibly hundreds, of millions of years that plants and animals are thought to have existed is a very brief time. Palaeopathology, by studying morbid processes over a great period, should help in solving present problems. The oldest known tumour of bone, a haemangioma of the vertebrae of a large dinosaur, forms the frontispiece, and there is a figure and an x-ray picture of the oldest known fracture, in a long-spined reptile of the Permian period.

In the chapter on disease and injury in fossil man the absence of any definite evidence of syphilis is pointed out, and the tuberculum of Carabelli is shown to be a dental anomaly found in fossil man and, though hereditary, quite independent of syphilis. Among the ancient Peruvians, who with the North American Indians and the ancient Egyptians are the only primitive peoples whose pathology has been much investigated, the occurrence of uta, a disease then and sometimes even now mistaken for syphilis, makes it difficult to decide as to the existence of the latter disease. In the interesting account of primitive surgery, which grew out of shamanism, or the efforts of the shaman, medicine man, or priest to let out evil spirits, an account of prehistoric trephining, common 10,000 years ago in the Neolithic period, rightly receives attention; it was frequently performed for headache and often more than once.

In conclusion, it may be said that this well written book is a useful introduction to this comparatively new and expanding subject.

### ATOMIC STRUCTURE.

IN *The A B C of Atoms* Mr. BERTRAND RUSSELL has been as successful as is perhaps possible in presenting the new theory of the constitution of the atom and all that it implies for the comprehension of the average educated person. The book is not long; the first part goes over the general ground traversed by Sir Ernest Rutherford in his presidential address to the British Association (BRITISH MEDICAL JOURNAL, September 15th, p. 474). So far the matters discussed can be more or less visualized, although Mr. Russell warns his readers that

"Our imagination is so incurably concrete and pictorial that as soon as we depart from the language of mathematics we have to express scientific laws in a language which asserts much more than we mean to assert."

"We speak," he continues, "of an electron as if it were a little hard lump of matter, but no physicist really means to assert that it is. We speak of it as if it had a certain size, but that also is more than we really mean. It may be something more analogous to a noise, which is spread through a certain region, but with diminishing intensity as we travel away from the source of the noise. So it is possible that an electron is a certain kind of disturbance in the aether, most intense at one spot, and diminishing very rapidly in intensity as we move away from the spot. If a disturbance of this sort could be discovered which would move and change as the electron does, and have the same amount of energy as the electron has, and have periodic changes of the same frequency as those of the electron, physics could regard it as what an electron really is without contradicting anything that present-day physics means to assert."

The real trouble begins for Mr. Russell and his readers when he gets to the theory of quanta, and Bohr's application of it to the atom. There are some who can understand mathematics and some who cannot, just as some have fair hair, and some have not: it is as absurd for the mathematician to despise the non-mathematically minded as it would be for the dark man to condemn the fair because of the deficiency of pigment in his hair. Mr. Russell very nearly succeeds in avoiding mathematics altogether, pre-

sending his grateful readers with the final conclusions the mathematicians have reached. He leaves aside almost completely the effect these theories are likely to have on chemistry, thinking, perhaps, it is a subject for the future; but as Sir Ernest Rutherford said, there can be little doubt that the next decade will see an intensified attack by physicists and chemists on this very important subject of molecular structure. Certain investigations already made favour the idea that shared electrons play a part in the electronic structure of two combined atoms.

### THE WASSERMANN REACTION.

If any member of the medical profession is making a hobby of collecting the different methods, modifications, and innovations of the Wassermann reaction he must secure a copy of Dr. G. RODILLON's little book, *La Réaction de Wassermann réduite Simple et Précise*.<sup>8</sup> Therein he will find an account of Dr. Rodillon's method, and it may even happen that amongst the methods described he may find one or more that are new to him. Dr. Rodillon's book is of modest design; he does not commence by denouncing all his predecessors, but generously does justice to nearly twenty methods older than his own. Even for his own method his claims are modest, for he declares that if serologists do not feel inclined to discard other methods for this, he will be happy if they will experiment with it as a control to them.

The other methods described in this book require no comment, for those that have merit are already well known and are described in standard textbooks. The novelty of the author's method consists in the fact that he divides the patient's serum into two parts; one part (four-tenths of the whole) is inactivated for five minutes at 56° C. and the other part is not inactivated and provides the complement. The only ingredients required for the test are the patient's serum, diluted antigen, normal saline, and sheep's red cells. His method, therefore, belongs to that group of modifications of the Wassermann reaction which dispense with either complement or amoebocyte derived from other animals and employ the notoriously variable quantities of these substances present in the patient's blood.

### NOTES ON BOOKS.

THE admirable little book entitled *The Health of the Runabout Child*<sup>9</sup> by Dr. WILLIAM PALMER LUCAS is aptly summarized by the author's phrase, "The journey from mother's lap to the school gate." It is an excellent book on the upbringing of the toddler. The chapters discuss in simple and very clear language the effect of heredity, the physical and mental standard which should be expected at each year's end, and what to beware of in the period from 2 to 6 years. The physical requirements and training of the child are expatiated upon, and a variety of good diet tables is added to the chapter on feeding. The author urges the necessity for community effort for health along the lines of prevention of disease, and quotes from Mr. Hoover: "Every child that is a delinquent in body, education, or character is a charge upon the community as a whole and a menace to the community itself." Emphasis is also laid on the mental training of the runabout child, whose psychology is briefly touched upon. "Play and work are simply attitudes of mind toward life." We strongly recommend this book to all intelligent parents and to others who also realize the responsibility of setting the feet of little children on the right path.

The second edition of *Abdominal Surgery for Nurses*,<sup>10</sup> by Mr. HAROLD BURROWS, will continue to be of great use to nurses who are interested in accomplishing their work intelligently and helpfully. The section dealing with shock has been rewritten and the entire book brought up to date. Simple and clear instructions and explanations are given for the guidance of the nurse in the more common abdominal operations. The aim of the author is to instruct her not only to be aware of possible complications incidental to abdominal surgery, but to explain to her the line of treatment of the surgeon.

and conjectures of science, and this was obviously the method followed by the school of Salerno, for whose physicians and pupils the literary habit of mind was attractive. A leading Salernitan recommended verse as a medium for medical and surgical statement. The lecturer could not accept the view that the metrical shape was preferred because it offered a means of committing didactic information to memory; there must have been a great deal more than that in the medical poetry of the school of Salerno. He mentioned the *Regimen Sanitatis*, by John of Ailhan, addressed to laymen, not to the faculty, but extensively copied, and at last published in English in 1607. It was impossible to believe that this was not a definitely literary enterprise. Evidently the influence of the Salernitan school of Salerno.

*Sir Thomas Browne and his Contemporaries.*

Abundantly taking his audience to England in the seventeenth century, the lecturer remarked the complaint of a Scottish physician of the age of Shakespeare that the Latin language was not friendly to the sacred founts of the medical art. This was a great discovery in an age when it had been as indecorous to write of physic in any language but Latin as to walk in the streets without a wig. The illustrious Ambrosio Pare wrote almost ostentatiously in his own French, and it was after the works of Pare had been translated into English early in the seventeenth century and had influenced our physicians to express their views in their native tongue that, whether as coincidence or result, Sir Thomas Browne began to compose his *Religio Medici*. That famous book was the earliest in which the harmony between the physician and the man of letters bore the test of scientific training and to combat the prevalent worldly belief that the anatomist could have no plenty.

In the closing year of the Commonwealth there appeared a medical poem in English, *The Plague of Athens*, not, however, written by a doctor, but by a clergyman, Thomas Sprat, afterwards Bishop of Rochester. What was really in Sprat's mind was not the record of Thucydides, but the terrible and unprecedented epidemic which had recently laid Naples waste. It was an extended poem; one of its suggestions was that the doctors themselves helped in increasing the number of his young man's days. John Locke, in his *Essay on the Human Understanding*, introduced views of health to which no philosopher would have given literary form half a century earlier. Locke's friendship with Sydenham was not to be overlooked in this connection, nor the strong approval given by the latter to a man of letters who seemed never to have taken his medical degrees. Locke was a figure whom neither the Royal College of Physicians nor an Academy of Letters (if there were one) could officially recognize; both as writer and physician he was the amateur incurate; nevertheless, he appeared at this critical moment to supply a valuable instance of the growing harmony between literature and medicine. When Browne with his divine ecstacy and Locke with his tolerant candour had taught the world to treat ideas as the anatomist treated the human body, the professions were brought into a union which could never be broken up again into the discord of the Middle Ages.

*Sir Richard Blackmore and Sir Samuel Garth.*

When the lecturer was considering this subject, the eminent Harveian Librarian of the College said jocosely, "I suppose you will resuscitate Sir Richard Blackmore in their hands, but an epic poet not even Phosphorus Apollo could resuscitate."

The reign of Queen Anne, with all its short far more cultivated and humane than any a The physician was welcomed at all clubs and where he introduced an element of humanity and his society was equally congenial to the members of the immortal band—Gay, Steele, and others. John Arbuthnot was an Aberdonian in London, and owed his success and his count physician to an accident at Ipsom, the only doctor available to attend a private quarter of a century he was a prince in the wit, to which he added a lustre of his quarter of a century he was a prince in the wit, to which he added a lustre of his spoke of him as a star which looked all fire, but never with his literary all bonnity, all gentle influence. He fell with whom he could still afford the poet's half-p and a warm welcome.

Of the other poetical physicians and doctors of the eighteenth century it would be entertaining to Some of them had never been received within the College—John Armstrong, for instance Goldsmith. But he would not expatiate on their successors, right down to our living Po who was a Fellow. He would like to close w the great and gentle John Arbuthnot, w the friendship between literature and medicine the friends had chosen to perpetuate his relation of the two professions in sculpnary oratory, he thought that a statue of the ar- History of John Bull (Arbuthnot), with bu Steele, and Gay at the corners, but as an epic poet not even Phosphorus Apollo could resuscitate."

*John Arbuthnot, Physician and Poet.*

The reign of Queen Anne, with all its short far more cultivated and humane than any a The physician was welcomed at all clubs and where he introduced an element of humanity and his society was equally congenial to the members of the immortal band—Gay, Steele, and others. John Arbuthnot was an Aberdonian in London, and owed his success and his count physician to an accident at Ipsom, the only doctor available to attend a private quarter of a century he was a prince in the wit, to which he added a lustre of his quarter of a century he was a prince in the wit, to which he added a lustre of his spoke of him as a star which looked all fire, but never with his literary all bonnity, all gentle influence. *The Public Schools and the Great War (1914-1919),*<sup>1</sup> by A. H. H. M., contains a list of 362 officers in the various services, excluding the navy except the Royal Naval Division and the Marines in land operations, who received the honour of knighthood or higher distinctions. Of those 362 officers, 254 were educated at public schools, and 48 were serving in medical capacities or with the Red Cross. A list of the various schools is headed by Eton with 35 knighthoods or higher distinctions, followed by Wellington with 24, Marlborough with 17, Cheltenham with 15, Harrow with 14, Winchester with 13, and Charterhouse and Clifton each with 11. Of all the officers who served in the armies of the British Isles, an average of about 13.5 per cent. lost their lives as compared with about 10 per cent. in the ranks, but among the great public schools the percentage was in almost every instance not less than 20. This inquiry was not extended to the navy in general because boys pass into that service at an age which precludes their having been at a public school, except possibly for a very short time.

*The Medical Clinics of North America* is a periodical published every other month. The first number of the seventh volume is an octavo of 314 pages, and contains a series of twenty-eight papers from the Mayo Clinic and the

Mayo Foundation for Medical Education and Research. Among the papers are four dealing with insulin and its use in the treatment of diabetes. The periodical is published by the W. B. Saunders Company of London at the price of 55s. a volume in paper or 75s. bound.

Under the title of *Pour Passer le Temps*, by "The Bagler," Dr. ALEX. FRASER, of Burnage, Manchester, has collected a number of verses and short notes which he wrote in 1917 and 1918 to amuse his friends in the 57th General Hospital, B.E.F., at Boulogne, and later at Mussau, near Marseilles. The verses illustrate the fine spirit of camaraderie that existed in the hospital, and should recall pleasant memories to readers who were upon its staff. The little volume is well produced, and is published by Messrs. Sherratt and Hughes, Manchester, at the price of 2s. 6d.

*Milton Agonistes: A Metaphysical Criticism,*<sup>2</sup> by Mr. E. H. VISIAK, is the work of a devoted student and admirer of the author of *Paradise Lost*. He seeks to show that whereas Shakespeare's individuality is in abeyance in his writings, Milton entered the dream domain of his genius as a self-conscious artist, with the result that his characters became himself, not he his characters, and his personality is plainly imprinted upon his works.

## NoVa et VeteRa.

### A CONTRIBUTION TO THE HISTORY OF ST. GEORGE'S HOSPITAL.

THE foundation of St. George's Hospital, as is well known, originated in a difference of opinion among the Governors of the Westminster Hospital in 1733. That institution had outgrown the building in York Street, occupied since 1720, and in 1733 it became necessary to find larger premises. The majority of the Governors decided to purchase a house in Thomas Street as an addition, but this was contested by a small but influential minority, which included the consulting physician, Sir Richard Mead, and the three principal surgeons, one of whom was William Cheselden, who contended that Lanesborough House, then standing near Hyde Park Corner, was "better adapted for a hospital than any other available site on account of the strength of the building and of the airiness of the situation."

Both Sir Richard Mead and Sir Hans Sloane took a personal interest in the new institution, and it was opened with 30 beds—soon increased to 60—on January 1st, 1734. An interesting document, which appears to have been hitherto unknown to the present authorities of St. George's, has recently been discovered, and is now in the Wellcome Historical Medical Museum. It consists of a folio sheet of three printed pages with a fine woodcut headpiece and initial, and throws an interesting light on the foundation of the hospital. It reads as follows:

AN ACCOUNT of the Occasion and Manner of Erecting the Hospital at Lanesborough House, near Hyde-Park-Corner. Published by Order of the General Board of GOVERNOURS there, Wednesday, February the 6th, 1733.

Several well-disposed Persons having long observed that there was no Hospital within the Liberty of Westminster, for the Relief of the many poor, sick and lame Objects that offered; and that such an Hospital was absolutely necessary in so large and populous a City; those in London being by no Means sufficient: They therefore agreed to set on Foot a Subscription for an Infirmary there, to relieve such poor, sick and lame Persons as should appear to the Subscribers to be proper Objects of Charity.

Accordingly in the Year 1719 a Subscription was opened, and a House was taken and fitted up in Petty France,\* which being found to be too small, they in the Year 1724, removed to Chapel-Street, where they have ever since continued. In both these Places great Numbers have been cured, as appears from their printed Accounts, under the Care, and by the Charitable Assistance of Dr. Alexander Stuart, Physician to Her Majesty, Dr. George Lewis Teiffer, Physician to His Majesty's Household, and Dr. William Wafer, as Physicians; and Ambrose Dickens, and Claudius Amyand, Esqs. Serjeant Surgeons to Her Majesty, and William Cheselden, Esq; Surgeon to Her Majesty, as principal Surgeons, and Mr. James Wilkie as Surgeon in Ordinary. These Gentlemen were all subscribers to this Charity; and to their concurring Labours the Society have always hitherto most thankfully acknowledged the Preservation of the Lives of their Patients, under God, to be owing.

About two Years since the Stock of the Society encreasing beyond Expectation, and their House being still too small, as well as old and ruinous, it became necessary to remove; and therefore Advertisements were publish'd by Order of the Board for several

Weeks together, enquiring after a large and substantial Building, in an airy Situation, within the City, or Liberty of Westminster.

At Length some Houses of Mr. Green's in and about Castle-Lane, in the lower Part of Westminster, and Lanesborough House, in the higher Part of it, being propos'd to the general Board, a Question arose which should be preferr'd. The Majority were for the Former; and they accordingly voted that Mr. Green's Houses were convenient for them, and that Lanesborough House was not so; and they appointed a Committee finally to agree

with Mr. Green. The Minority, tho' over ruled, were not convinced. Among the Minority were all the above-named Physicians and Surgeons, together with several who had been concerned in the Charity from its first Establishment, and some who had laid the Foundation of it several Years before, besides many others who had been very active and useful Instruments in carrying it on since. All these (whose Subscriptions at Lady-Day last, with those of their Friends, brought in by them, have been computed to amount to above the Half of the Whole) were of Opinion that there was no Place about this Town more proper for their Purpose than Lanesborough House.

An Hospital there, on Account of its Neighborhood, could give no offence to any one; the Building was large and strong, and many of the Rooms were so contriv'd, as if they had been built for the Uses to which they were now to be apply'd; it was near enough to the Town to be supply'd with all the Necessaries that would be wanting, so near that the Governours might attend without Inconvenience, and yet far enough for the Patients to have the Benefit of a Country Air, which, in the general Opinion of the Physicians, would be more effectual than Physick in the Cure

\* Now called York Street, Westminster.

of many Distempers, especially such as mostly affect the Poor who live in close and confin'd Places within these great Cities.

For these Reasons they resolved to take Lanesborough House, and if possible to persuade the Majority to join with them. But finding at a subsequent general Board, that their Brethren were absolutely determin'd against it, and that it was in vain to hope for their Concurrence: They, the Minority, agreed that they ought not to let slip so advantageous an Opportunity of removing, and therefore they completed their Agreement at £60 a Year, resolving to carry on the same Charity there. Thereupon the Physicians and Surgeons acquainted the Board that Lanesborough House was taken; that they were resolved to carry their Charity and Attendance thither; that they could not attend both, but they would attend in Chapel-Street 'till other Physicians and Surgeons should be provided; and if at any Time their Assistance should be wanted, they would be ready to attend when desir'd.

Thus began the Separation which has prov'd of great Service to the Charity; for now, by the Zeal and Emulation of both Societies, they will probably be able to entertain above four Times the Number of Patients they have hitherto done. Immediately after this, the Society in Chapel-Street chose other Physicians and Surgeons, and the Gentlemen at Lanesborough House set themselves vigorously to work to lay the Foundation of their new Hospital. For that Purpose they met almost every Evening, and procured not only the By-Laws of all the Hospitals about the Town, but also the By-Laws of several Hospitals in foreign Parts, out of which to collect such Rules and Orders as should best suit their Occasions; and having well weighed and consider'd the Undertaking, they form'd themselves into a regular Society on Friday the 19th of October, 1733.

Since that Time they have collected and digested a regular Body of Laws for the Government of themselves, their Servants, and their Patients, extracted for the most Part from the several By-Laws that have been laid before them. And as they had Reason to apprehend that an Inconveniency might arise by permitting small Subscribers to be Governours; no Man is qualify'd to be a Governour there that does not contribute £5 a Year; and even then he must be proposed a Fortnight before he can be chosen, which is at last done by a Ballot. Such is their Caution in the Choice of their Governours, of whom nevertheless they have already about 150, and from whom, as well as from several Ladies of Quality and Distinction, they have received very generous and beneficent Contributions.

The Hospital is now fitted up and made much more compleat than could have been expected out of a Dwelling House: It will at present contain 60 Patients; but as the Boundaries of their Ground will admit of new Buildings for several spacious and airy Wards, large enough to lodge some Hundreds of Patients better and more commodiously than any other Hospital about this Town; they propose to erect such Buildings as soon as their Circumstances shall enable them.

They began to receive Patients on New Years Day last, and several In and Out Patients were then received, and they continue so to do every Wednesday Morning until Ten of the Clock: They will admit as many In Patients as their House will contain, and Out Patients according to their Ability.

They have in their House an Apothecary, and a compleat Shop; and all the Physicians, Surgeons, Apothecaries, Chemists and Druggists, are a Committee to buy the Drugs and other Materials, for making the Medicines there; under whose Inspection all the Medicines are made: And the following Apothecaries, viz., John Warren, and Daniel Graham, Esqs. Apothecaries to His Majesty, John Allen, Esq; Apothecary to His Majesty's Household, Mr. Isaac Rand, Botany Professor of Chelsea-College, Mr. John Clark, Mr. Andrew Mitchel, Mr. Thomas Graham, and Mr. James Fraser attend by Rotation as Visitors, to see them duly dispensed according to the Prescriptions of the Physicians.

Among other Regulations, the following one is proper to be here inserted, which is, That no Person belonging to this Hospital presumes, upon Pain of Expulsion, to take of any In, or Out Patient, any Fee, Reward, or Gratification whatever, directly or indirectly, for any Services received from this Hospital, either while they are under the Care of the House, or after they shall be discharged.

Dr. Stuart, Dr. Wafey, Dr. Broxholme, Dr. Burton, and Dr. Ross, who are all Governours, have consented to be the acting Physicians there, without Fee or Reward; the Patients are visited by them 3 Times a Week, they all meet there every Saturday together, and they attend by Rotation every Wednesday Morning at 9 to examine the Patients that are recommended. Mr. Serjeants Dickens and Amyand, and Mr. Cheselden, have consented to be principal Surgeons, and Mr. Wilkie and Mr. Middleton are the Surgeons in Ordinary: These Gentlemen are also Governours, and serve without Fee or Reward. Several eminent Divines have agreed to attend the Patients daily, for their Spiritual Comfort and Instruction; and two of the Governours are Weekly appointed, who attend every Day as Visitors to hear Complaints, and to see the Orders of the Board punctually obeyed.

As the Business of this Hospital hath been too much for the Governours to manage in a Body, they have appointed several Committees, who all Act with that Zeal, Integrity, and Application as become Men who have only in View the Honour and Service of Almighty God, the publick Happiness and Prosperity of their Country, and the Support and Relief of their fellow Creatures in Distress.

N.B.—The great Numbers of Objects that daily offer, are sufficient to shew the Usefulness and Necessity of Hospitals of

this Kind: And tho' Guy's Hospital, a noble Endowment, hath been lately erected, yet more are still visibly wanted: And 'tis hoped the Example of these Gentlemen may be a Means to induce other well-disposed Persons to make this Kind of Charity more diffusive, and extend it to other Parts of the Kingdom.

P.S.—As the Physicians attend every Wednesday Morning punctually at Nine, the Contributors to this Charity are desired to direct the Patients to be there at that Hour, the Board having made an Order that none shall be received after Ten.

The staff of St. George's Hospital has always been peculiarly rich in the possession of men who have achieved high positions in both medicine and surgery. The names of John Hunter, Matthew Baillie, William Heberden, Thomas Young, William Cheselden, Benjamin Brodie, and Prescott Hewett are but a few of those who have added lustre to its roll.

C. J. S. THOMPSON, M.B.E.

## THE GENERAL ELECTION.

The following is a list of medical candidates at the General Election and of the constituencies in which they are offering themselves so far as we are at present able to ascertain. An asterisk indicates that the candidate represented the constituency in the Parliament just dissolved.

At the present stage the list cannot be complete, and we shall be glad to receive additions and corrections.

- Dr. H. B. Bates (U.), Newton, Lancs.
- Dr. Ethel Bentham (Lab.), Islington East.
- \*Sir George A. Berry (U.), Scottish Universities.
- \*Dr. W. A. Chapple (L.), Dumfries.
- Dr. R. Dunstan (Lab.), Ladywood, Birmingham.
- \*Dr. W. E. Elliot (U.), Lanark.
- Dr. M. I. Finucane (L.), Westminster.
- \*Dr. F. E. Fremantle (U.) St. Albans.
- Dr. O. Gleeson (Lab.), Portsmouth South.
- Dr. L. Haden Guest (Lab.), Southwark North.
- Mr. Somerville Hastings (Lab.), Reading.
- Dr. G. B. Hillman (U.), Nормanton, Yorkshire.
- \*Dr. L. G. S. Molloy (U.), Blackpool.
- \*Dr. J. E. Molson (U.), Gainsborough.
- Dr. H. B. Morgan (Lab.), Camberwell North-West.
- Dr. J. H. Morris-Jones (L.), Denbigh.
- Dr. A. G. Newell (L.), South Tottenham.
- Dr. R. L. Ridge (L.), Enfield.
- \*Sir Sydney Russell-Wells, M.D. (U.), University of London.
- \*Dr. A. Salter (Lab.), Bermondsey West.
- Dr. R. W. Simpson (L.), Newcastle-upon-Tyne North.
- Dr. G. E. Spero (L.), Stoke Newington.
- \*Dr. T. Watts (U.), Withington.
- \*Dr. J. H. Williams (Lab.), Llanelli.
- Dr. R. M. Wilson (L.), Saffron Walden.

Sir Henry Craik, K.C.B., is standing for re-election as one of the representatives of the Scottish Universities.

THE appeal for a quarter of a million pounds to defray the cost of the erection of the new science wings of the University College of South Wales and Monmouthshire at Cardiff has now brought in £156,000. Several important donations were announced on November 20th. Lord Glanely gave £10,000; several sums, to spread over seven years, were promised, including £28,000 from Sir David R. Llewellyn, £7,000 from Sir Henry Gethin Lewis, and a like amount from Mr. H. Seymour Berry.

THE United States Naval Medical Corps now numbers 751 commissioned officers, and it is stated by the *Journal of the American Medical Association* that even with the reduction in strength and appropriations for the navy at present there is a shortage of forty-nine officers below the Government allowance. The United States Army Medical Corps is also stated to be at present thirty-six medical officers short of its quota.

THE fourth international Congress of the History of Medicine will be held at Geneva from July 20th to 25th, 1925, under the presidency of Dr. C. G. Cumston. Further information can be obtained from the general secretary, Dr. A. de Peyer, 20, Rue du Général Dufour, Geneva.

## British Medical Journal.

SATURDAY, NOVEMBER 24TH, 1923.

### THE DECISION OF THE PANEL CONFERENCE.

LAST week we announced briefly the result of the Special Conference of Representatives of Local Medical and Panel Committees held on November 14th to consider the Minister of Health's revised offer. This week we publish in the SUPPLEMENT a full report of the discussions that led up to the unanimous decision to accept the Minister's offer, including his alternative proposal for a special Court of Inquiry. An important, though subsidiary, decision was the acceptance on behalf of rural practitioners of mileage grants for 1924 of £250,000 for England and Wales and £46,000 for Scotland. The Conference, in view of these decisions, authorized the Insurance Acts Committee to deal with the withdrawal of resignations collectively, and arrangements (of which every insurance practitioner has been, or will be, notified this week) are being made to carry out this instruction with the least possible delay. Each practitioner should already have received from the head office of the British Medical Association a form of withdrawal of resignation in respect of each panel list on which his name appears.

The decision of the Panel Conference has been accepted without reservation by the Minister of Health, and the Insurance Acts Committee will now devote its energies to the effective presentation of the case of the medical practitioner for an adequate capitation fee. The profession, by the decision of the Conference, has pledged itself to accept the finding of the Court of Inquiry, and it will become the duty of the British Medical Association to use all its influence with members of Parliament to ensure the passage of the bill in which the Court's award is to be embodied. Owing to the dissolution of Parliament and the impending general election it will not now be possible for the Minister to fulfil his promise to go to Parliament for the necessary legislative sanction before the close of this year. Sir William Joynton-Hicks has undertaken to set up the Court of Inquiry at the earliest possible moment, and it may be expected that the sittings of the Court will begin immediately after its appointment, and that as soon as it has concluded its inquiry its decision on the amount of the capitation fee will be made known. The fee awarded will have effect as from January 1st, 1924. In the unexpected circumstances which have arisen owing to the sudden dissolution of Parliament it would seem that insurance practitioners will have to begin the new year without a statutory assurance as to the amount of the capitation fee for 1924. But whatever the complexion of the new Parliament it seems unlikely that it will reject the recommendation of the Court, the appointment of which has been formally reported to the House of Commons.

Although the capitation fee for 1924 is as yet an unknown quantity, it is not too soon, we think, to express satisfaction with the course of events. The past two months have been a period of great anxiety for a large section of the medical profession, calling

for self-restraint and courage on the part of the rank and file, and for wisdom and leadership in those who represent them. The terms of the Minister's final offer justified the unanimous refusal of his first offer. Although complete satisfaction has not been obtained, the solidarity of the profession and the statesmanship of its leaders secured from the Minister explicit assurances on certain matters of vital importance to the future of medical practice under the Insurance Acts; the decision of last week's Conference has done much to consolidate these gains. The Minister's new offer had to be accepted or rejected as a whole with one or other of the alternatives in regard to remuneration, and it was imperative that a decision should be reached both upon the whole offer, and as between (a) a guaranteed fee of 8s. 6d. for five years, or (b) a separate and immediate inquiry into the appropriate capitation fee for 1924. Upon the larger issue representatives of insurance practitioners had a clear lead from their executive body—a lead endorsed by their constituents; as between the two alternatives, (a) and (b), the Committee's recommendation was less positive. Having had the realities of the situation put plainly before it the Conference rose to the occasion, and its choice has, we believe, reflected the feeling of the great bulk of those on whose behalf it voted.

The insurance crisis may not be over yet, but in accomplishing so much in such difficult circumstances the medical profession has done well. Two matters seem, in particular, to call for congratulation. In choosing a Court of Inquiry the Conference took the logical course and showed confidence in the strength and justice of its case for adequate remuneration. This decision to abide by the award of an impartial arbitration, coupled with the remarkable unanimity shown by 95 per cent. of resignations from the panel, has not been without its effect upon the Ministry of Health, on public opinion, and doubtless also on the Approved Society officials. The public has understood the determination of the profession to be free to give, unhampered, the service for which it exists, and has applauded the outcome of the Conference. This is no small gain. Moreover, professional solidarity led to a new offer by the Minister, and it gave practitioners confidence in themselves and in each other; the decision to submit the money question to arbitration has done the profession good in the eyes of the public. These two advantages may fairly be claimed as due in large measure to the organization, both central and local, of the British Medical Association. The machinery has stood the test, and the united action of insurance practitioners testifies to the trust reposed in the Association by the general body of the profession. This trust must be continued, for the award of the Court of Inquiry will probably be for one year only.

### BIRTH INJURIES OF THE CHILD.

EVIDENCE is accumulating that injuries to the infant during parturition are commoner than has hitherto been supposed. Dr. Ehrenfest of St. Louis has recently<sup>1</sup> made the categorical assertion that "in at least 40 per cent. of all autopsies, properly performed on all stillborn infants and those dying within the first few days after birth, intracranial traumatic lesions of some sort are discovered." Yet the returns of the cause of death in current statistics

<sup>1</sup> *Birth Injuries of the Child*. By Hugo Ehrenfest, M.D., F.A.C.S., St. Louis, Mo. Gynecological and Obstetrical Monographs. New York and London: D. Appleton and Co. 1922.

of his statement he pointed out that the National Convention which met in 1917 to draft a constitution for the Irish nation recommended that the vacancies occupied in the public medical services should be filled by competitive examination. In the scheme of medical services formulated by the Irish Public Health Council in 1920 provision was made for filling medical vacancies on a civil service basis, and in 1910 a referendum of the Irish people showed, almost by a unanimous vote, that it was in favour of filling all vacancies in the public medical services by competitive examination. The General Council of County Councils, as late as this year, made similar recommendations. It was understood a Public Health Bill would be introduced shortly under which medical officers of health would be appointed. Personally, he would rather see the bill torn into shreds than have it passed, if it meant putting into office men who were not efficient.

#### A TREASURER'S SCORE.

The Ministry of Home Affairs (Northern Ireland) held an inquiry seven months ago in connection with the tuberculosis scheme in the County Fermanagh. The inquiry was ordered in consequence of allegations that the scheme was too costly, and that in particular the travelling expenses of the medical officer and the cost of nursing were excessive. It will be remembered that the Commissioner, prior to the inquiry, decided to limit the medical officer's travelling expenses to a sum of £120 a year, and to dis-

pense with the services of the whole-time nurse who was to have been employed under the scheme. The medical officer, Dr. Timoney, was originally appointed at a salary of £500, which was intended to include the cost of travelling, but later he was allowed second-class train fare and independence for motor hire, on the understanding that he would use the train whenever possible. The trouble with regard to his expenses appears to have arisen because Dr. Timoney never took the train, but used his own motor car on all occasions, charging mileage for its use, and the Commissioner and others concluded that the ratepayers were thereby put to unnecessary expense. From the figures which have been furnished, however, it does not appear that there are sufficient grounds for holding that the use of the motor car by Dr. Timoney, to the exclusion of the train, has resulted in increased cost to the ratepayers. It seems clear that Dr. Timoney's plan of using his own motor car to visit all cases is certainly not uneconomical. The sum of £120 per annum proposed by the Commissioner in the circumstances is inadequate, and the Ministry considers it fair that he should be paid his actual travelling expenses, and in order that these may be properly checked be should be supplied with forms similar to those used by travelling officers of Government Departments, in which he should furnish a weekly report, in diary form, of the work done by him and the expenses incurred. The mileage allowed to Government officers, which is sevenpence a mile for a four-wheeled motor car with four ordinary seats and over 11 horse-power, with lower rates for smaller cars. Nothing is a necessary part of any scheme for the treatment of tuberculosis, and if adequate facilities were provided for all parts of the county the cost of nursing would not be less, but considerably more than it is at present. At the same time the Commissioner appears to have been justified in considering that the cost of the whole-time nurse employed in Enniskillen was excessive in proportion to the work done. As regards the general cost of the scheme, the total expenditure for the half-year ended September 30th, 1922, was £1,576 11s. 2d, and for the year ended March 31st, 1922, it was £1,904 14s. 6d. The average cost for the eight years April 1st, 1914, to March 31st, 1922, was £2,119 14s. Deducting receipts, the average cost was £1,712 18s. 10d. a year, and as half is recovered by the Government the average cost to the rates was £856 9s. 5d. a year, representing a rate of less than one penny in the £ on the valuation of the county. The average number of cases under treatment in a half-year ended September 30th, 1922, was 269, of these 176 were dispensary cases, 52 institutional cases, there are

### SCOTLAND.

#### NEW MATERNITY HOSPITAL FOR EDINBURGH.

On the invitation of the directors of the Edinburgh Royal Maternity and Simpson Memorial Hospital, a private conference of delegates appointed by the Town Council, the Board of Health, the Royal Infirmary, the University, the Royal Colleges of Physicians and Surgeons, and the medical staff of the hospital, met the Board of the hospital on November 16th, in the Council Chambers, to consider the question of providing an enlarged and up-to-date maternity hospital for Edinburgh. Dr. J. G. Nasmyth, chairman of the directors, who presided, explained the circumstances which made the provision of a new hospital necessary. After full discussion it was unanimously resolved that a new maternity hospital, with a minimum of 150 beds, is an urgent necessity if the maternity needs of the city and district and the training of students and nurses are to be adequately provided for. A committee representing the various bodies was appointed and instructed to report on the subject of a new hospital generally, with special reference to suitable sites and the future relations between the hospital and the Infirmary. After the receipt of this report a public meeting will be called.

In conclusion, the Ministry expresses the hope that the result of the inquiry will be to clear away many misconceptions regarding the scheme and to show that, while it is not as complicated as it might be, it fulfils a useful purpose and enables much good work to be done in preventing the spread of tuberculosis.

#### INSULIN.

The second meeting of the Ulster Medical Society was held in the Medical Institute, Belfast, on November 6th, when the President, Professor Symonds, was in the chair, and Dr. John Kilroy read a paper on certain aspects of the physiology of the pancreas. He accounted for the long delay in elucidating the full function of the organ by its double action: in many fishes there were two separate organs. He gave an account of the preparation of insulin, of its fate in animals, and of its standardization; it was found in the urine as well as blood and pancreas, but not elsewhere. The experiments relating to the cause of control-diabetes in hypoglycaemia, and to the relation of fat and carbohydrate metabolism, and to many other problems, were narrated. Dr. Sinclair Miller of Hartogave read a paper on the use of insulin in diabetes mellitus. He gave a description of the clinical aspect of the use of insulin, the precautions to be observed, the necessity of full examination for the estimation of blood sugar, and for the regulation of diet according to results. The treatment of mild, of medium, of severe cases, and of cases of renal glycosuria was illustrated by numerous charts thrown on the screen. Dr. J. A. Smyth, assistant in charge of the metabolic laboratory in the Royal Victoria Hospital, related the experience of the Royal Victoria Hospital in the use of insulin. He illustrated his remarks by charts of glucose tolerance in the normal, in hyperlipidism, pregnancy, in encephalitis lethargica, and cases of lowered sugar threshold. The treatment of the ordinary forms of diabetes and of exceptional forms and complications was commented on and illustrated by cases. Numerous patients were shown who had been admitted to hospital with very advanced symptoms, but now gave unmistakable evidence of good health and well-being. Drs. Calveit, McKisack, Morrow, and Burns briefly illustrated their very high appreciation of the papers, as illustrating the application of science to practice. Dr. Burns mentioned the case of a patient who had had a course of insulin with great advantage, but after a dose given some time later to deal with a slight relapse presented phenomena of anaphylaxis.

in America (as elsewhere) would lead to the conclusion that birth injury was very rare. There can be little doubt where the truth really lies. In the first place, very few yet realize the meaning of the asphyxias seen in the newborn, and even when the child recovers and grows perhaps to present the signs of Little's disease the trouble is as often as not ascribed to the asphyxia, whereas neither is primary but both secondary. It will be some time before knowledge of the very common happening of intracranial haemorrhages becomes really widely known, though such a paper as that by Dr. H. C. Cameron, published in this JOURNAL on March 3rd (p. 363), will help to draw greater attention to the subject. In the second place a man will hesitate very naturally before he ascribes the death of his patient's baby to injury. The very word has an ominous sound. A fatal injury seems to imply some fault on the part of the obstetrician. Yet practically every form and variety of birth injury has been discovered after an entirely spontaneous birth. This would appear at first sight to be an ample shield, but as a defence it is more in the nature of a smoke screen than of armour plate. For instance, there seems little doubt that injury to the child is very much commoner in an "assisted" birth than in one which is entirely spontaneous.

Dr. Ehrenfest considers that better knowledge of these injuries may in the future considerably modify obstetrical practice, and serve to curb the enthusiasm of those who practise forceps extractions, versions, and so forth with more zeal for the mother's comfort than the baby's welfare. In this respect the giving of large doses of pituitrin, causing the rapid descent of the head through a birth canal not yet sufficiently relaxed, or the giving of hyoscine, subsequently necessitating the use of forceps, may have to be reconsidered. Be that as it may, the time has come when we must realize that intracranial injury is the most important single cause of early death—either of stillbirth or of death soon after birth. We have recently in this country been made aware of this by the masterly report<sup>2</sup> of Dr. Eardley Holland to the Ministry of Health. He showed that more fetuses were killed by the complications of labour than died during pregnancy from maternal or placental disease. Only 16 per cent. of 300 fetuses were syphilitic, whilst of 167 fresh fetuses in no less than 48 per cent. tearing of the dural septa and cerebral haemorrhage had occurred. Dr. Ehrenfest deals at length with injuries of the head and neck, and, recognizing that no one obstetrician could possibly have a large enough experience of all varieties of birth injury to write a complete monograph upon them, he has drawn very largely on the literature.

Fractures of the cranial bones are usually produced by the promontory of the sacrum and hence affect the posterior of the two parietal bones. It is important to note that they may occur in unassisted labours, and Ehrenfest quotes a case of Hartmann's where a child was born just as the latter was about to apply forceps; it had a depressed fracture of the left frontal bone; subsequently it was ascertained that all of the mother's preceding six children had been born with cranial injuries. "One child, 6 years old, still showed a deep spoon-shaped depression over the left parietal bone." On the other hand, out of 25 cases of depression published in 1913 by Gfroerer and Hofmeier, 24 were breech extractions, mostly after versions—that is to say, were not spontaneous births. If there are no signs of an intracranial injury these cases may be left alone,

but it should be understood that "no signs" means "no signs after a most exhaustive clinical examination." If there are signs of haemorrhage within the skull the elevation of the fracture alone, whether by open operation or by means of such dangerous screws as Baumm's and some others, is not sufficient. "Kuestner employed Baumm's instrument," said to be "so constructed that an injury to the dura is impossible; the child died four days later; the dura had actually been perforated by the tip of the instrument; a large haematoma, responsible for the death, was however not found at the hole through the dura, but underneath the tentorium." Elevation of the depression by squeezing of the child's head between the knees, and so forth, is even more open to objection.

Dr. Ehrenfest refers to the classical paper of Seitz (1907) on the symptomatology of brain haemorrhages in the newborn, and to the paper of Beneke (1910) on tears of the tentorium cerebelli. He describes Beneke's *post-mortem* technique, whereby it came about that he was able to detect these dural lacerations, and goes on to give Beneke's and Pott's description of the nature and causation of these injuries. It is interesting to note that they were described first by Cruveilhier, and later by Virchow in 1850, and had been neglected for sixty years. The immediate cause of these tears is mechanical. The haemorrhagic diathesis seems to have been given too much importance as an etiological factor in these cases, though there is no doubt that such an entity exists and is sometimes operative. The mechanism described by Kundrat and Seitz (overlapping of the parietal and tearing of the veins entering the superior longitudinal sinus) accounts for but few of the cases. Beneke has shown the exact mechanism of the common tentorial lacerations—how the dural septa counteract the effect of lateral compression, and how severe or sudden compression may cause a stress too great for the falx to withstand when it tears the attached tentorium. These results have been confirmed by later workers, and incidentally the mechanics of the condition have been well studied and described by Eardley Holland in the monograph already mentioned, though here we failed to find reference to previous workers in this field. Benthin and then Seitz claimed that ill advised efforts to save the perineum when the head is forcibly pressed against the pubes may produce tentorial injuries. Dr. Ehrenfest remarks that in the numerous detailed records of severer brain injuries it is common to find that pituitrin has been administered, and believes that we have here cause and effect. The symptomatology of intracranial injury presents an interesting problem, but one most difficult to interpret. As a rule, newborn infants with haemorrhage are not easy to resuscitate and often have respiratory difficulties from bulbar embarrassment, especially in infratentorial haemorrhages. The infants are restless, cry almost incessantly, and often refuse to suckle; it has, indeed, been noted that the sucking reflex is commonly absent. They are pallid, may have convulsions, and sometimes the fontanelle bulges noticeably. The differential diagnosis of supra- (hemispherical) and infra-tentorial lesions is not easy. The treatment of the condition is still *sub judice*. Lumbar puncture is probably the most useful method at once for diagnosis and treatment, unless a haemorrhage can be localized with some show of accuracy to the surface of a hemisphere. It is very doubtful whether operation can ever hold out much hope for the serious haemorrhages in the posterior fossa. Injection of whole blood is worth trying.

<sup>2</sup> Reports on Public Health and Medical Subjects. No. 7. 1922. H.M. Stationery Office.

The table of puerperal morbidity should include all cases in which the temperature reaches 100° F. on the eighth day after delivery. Two of the bi-daily readings from the end of the first to the eighth day after delivery." In the table of puerperal morbidity should include all cases in which the temperature reaches 100° F. on any two occasions from the second to the eighth day inclusive; all deaths are included in obtaining the percentage of morbidity. At the Jessop Hospital, Sheffield, it is obtained from all cases "in the first eight days of temperature of over 100° F., occurring between the four-hour and excluding the first day." It is shown with and without deaths included. At

**PURPERAL MORBIDITY.**  
—In 1905 at the Annual Meeting of the Association suggested that a standard should be fixed for purpura morbidum. This was done by a small committee following published in the Supplement on May 1, 1906 (p. 261):

maguodsa.10 D

The International Physiological Congress. Edward Sharpey Schaffer presided last week over a meeting of the General Committee of the International Physiological Congress, held in Edinburgh. The secretaries reported that 462 names had been received from twenty nationalities—a larger number than attended any previous congress. The treasurer's account showed a small credit balance. Resolutions of thanks were passed to the late Lord Provost of Edinburgh, Sir Thomas, Bt., and to Lady Hutcheson for the part rendered the congress a success; to the printer, Messrs. W. & A. Brown, for the printing of the programme; to the University for promoting its interests; to the University for granting the use of its buildings and laboratories.

PREVENTION OF DIPHTHERIA.

A public lecture was recently delivered by Dr. H. O. H. Edinburgh, under the auspices of the Academy Parents' Association, on the prevention of the severity of diphtheria and had diminished it. In 1913 Shick had introduced a method by which it was possible to discover those who were susceptible. He had found that among newly born children 7 per cent. were susceptible, but in the first 5 years of life the susceptibility rose to 43 per cent., while between 5 and 6 years to 63 per cent.; among adults 90 per cent. were susceptible. The present scheme of treatment designed to restore to the boy or girl the normal state of the throat is the importance of this condition. The importance of the facts that in the past year 1913 of diphtheria were notified in Edinburgh, and had died. Of the cases notified 7,542 had been hospitalised at a cost of £30,504. Dr. Claude B. local superintendent of the City Hospital, who details the scheme in detail, said that he hoped attention would be turned to protection from whooping-cough.

Officers (Scotland) Bill, which provided for the appointment of a permanent Under-Secretary for Scotland, and would have reduced the number of the Board to three (save *ex-officio* membership of Executive Officers and other Civil servants issued a circular expressing the view that the duties of the Board altogether, and to the duties of the department to be discharged permanently had directly responsible to the Secretary of State and the Parliamentary Under-Secretary for Scotland).

[illegible]

**BUTYN AS A LOCAL ANAESTHETIC IN NOSE  
THROAT PRACTICE.**  
Sir,—Dr. Hill's article on this subject (British Medical Journal, November 10th, p. 876) is a valuable contribution to the comparative study of this new anaesthetic, which butyn is of interest in view of the fact that the position which butyn will take probably depend largely on its efficiency in nose and operations. There are one or two questions raised by Hill regarding difficulties in the acceptance of butyn as a substitute for cocaine regarding which I would like to make a few comments. Starting first with the cost, it is more expensive, it is true, but as only a small quantity is required this is of no practical importance, at least for ophthalmic use. A 2 per cent. solution can be bought in an ounce—that is, a penny will buy six drops, a quantity more than sufficient for most operations on the eye. The nose and throat probably more would be required even than the expense would not be prohibitive. Dr. Hill adds that in some of his nasal cases butyn fails to act, and he correctly adds that I made no mention of this occasional failure of butyn to anaesthetize; he continues: "On referring to Bulson's report I find that others have noticed certain individuals, not a large number probably, failed to respond to butyn." In my paper (British Medical Journal, January 13th, 1923) I made no reference to the occasional failure of butyn to act because I had not experienced it. Dr. Bulson's statement ("minds of Otolaryngology, and Laryngology, March, 1922) regarding this matter is not correct."

November 19th.

organization appointed, who, in fact of the members. The servants have time has arranged by a satisfactory for Rotunda, but only one would be so classed on either other hospital readings of the standard. I do not think any standard will give perfection, standard is effective for control in the individual, British Medical Association standard as a means of comparison, or for obtaining statistics. I would like to know the views of others on the readings and if opinion is in favour of a reading other members of the British Medical Association connect the one I adopt, I would fall into line; perhaps some of the hospital will give their interpretation of the Medical Association standard—I am, etc.

Injuries to the vertebral column have also to be considered; fracture of the cervical spine, usually at the level of the sixth vertebra, is the most usual spinal injury. Extension of the foetal spine is fraught with more danger than flexion, and it appears probable that the Veit-Smellie manoeuvre is not without danger of vertebral injury. Facial paralysis, injuries of the face and eye, injuries of the neck and sterno-mastoid muscle, have also to be reckoned with, and Dr. Ehrentest has dealt very ably with birth palsy—a subject which has excited the interest and controversial powers of so many orthopaedic surgeons. He separates the wheat from the chaff, and his summary of the subject is the best with which we are acquainted, though rather too much stress is laid on compression of the brachial plexus by the clavicle.

A pioneer task has been accomplished with skill, with tact, and with judgement. The subject of intracranial injury is one destined to loom very much larger than has been the case in the past, and its importance will compel acquaintance with its details. The symptomatology, the diagnosis, and the treatment of intracranial haemorrhage of the newborn is a comparatively new field, where much of great value to humanity remains to be reaped.

#### SANITARY MISSION TO SAMOA.

DR. P. A. BUXTON and Mr. G. W. HOPKINS sailed on November 15th by the Panama route for Samoa, where they are to inaugurate preventive measures against the prevalent filarial diseases on behalf of the London School of Tropical Medicine. The expedition has been sent at the suggestion of the High Commissioner of New Zealand, and it is anticipated that the personnel of the party will be enlarged in New Zealand by the inclusion of one or more undergraduate students from the local medical schools. When the New Zealand authority took over the Samoan Islands under mandate from Germany certain appropriations were made, and out of these a small medical service was organized. The health conditions in the islands have, however, proved to be very bad, and have become a source of much anxiety to the new Government. In 1918 the influenza epidemic carried off nearly one-third of the whole population. More recently dysentery has attained epidemic proportions, and tuberculosis is reported to be spreading with alarming rapidity. Playing a more insidious part in undermining the physique and initiative of the native Polynesians are the helminthic infections, filariasis and ankylostomiasis. The present state of matters is such that the future of the native races is imperilled, so that the development of the local natural resources may necessitate the introduction of Chinese and Indian labour, thus raising a new political problem of peculiar gravity for the Government of New Zealand. Apart from the drawback of their extremely inaccessible position, the Pacific islands present certain particularly advantageous features for the study of all the factors involved in the eradication of filarial infection. The conditions of life upon the atolls are of the simplest—although scarcely as idyllic as those vividly pictured by the reader of present-day fiction. The communities are small, numbering on many of the atolls only a few hundred. On the smaller islets the dense bush surrounding the villages resists the searching trade winds, and provides still and damp refuge for mosquitos, which are of few species although legion in numbers. Statistical surveys, which present almost insuperable difficulties in most tropical communities owing to the necessity of examining the blood at night, are here rendered easy, for the filaria of the Pacific is peculiar in that it exhibits no periodicity, and is

equally prevalent in the blood by day as by night. Much of the scientific data which must necessarily form the basis of the sanitary campaign about to be instituted has already been collected by an expedition from the Tropical School which visited this region in 1921-2. It was shown that of the six species of mosquitos in Samoa *Stegomyia pseudoscutellaris* was the efficient carrier, and occurred everywhere and at all seasons. Its chief-breeding places are provided by man in the heaps of coco-nut husks which accumulate from the making of copra, but the burrowings of the rhinoceros beetle and crevices left by Nature in the palms have also been implicated. According to present arrangements the mission will remain in Samoa for two years, but the chronic nature of filarial infection will necessitate the maintenance of the sanitary control in the experimental area for many more years before its influence or success is obvious. It is to be hoped that the New Zealand Government realizes the moral obligation it is assuming, and is prepared to ensure that the public-spirited initiative of the London School of Tropical Medicine in undertaking the experiment is not afterwards rendered futile. The mission is being financed from the Milner Research Fund, which is intended for the promotion of original investigations, and not to subsidize or replace local efforts in sanitation.

#### A MODERN MATERNITY HOME.

QUEEN MARY's Maternity Home, for the benefit of the wives and children of men who are, or have been, serving with His Majesty's Forces, was opened temporarily at Cedar Lawn in North End Road four years ago. In July, 1922, it was moved to permanent premises, built for the purpose and charmingly situated overlooking the White-stone Pond at the edge of Hampstead Heath. The handsome building is surrounded by a pleasant walled garden, and the wards have been planned to secure the fullest amount of sunshine and fresh air. The home accommodates 17 patients and the necessary nursing and domestic staffs; it contains two labour rooms, a nursery and an isolation room, and a well equipped laundry. The third annual report, forwarded to us by the chairman of the Committee of Management, Lady Bertha Dawkins, summarizes the first year's work in the new quarters, and gives some account of the kind of cases received. It appears that most of the patients seek admission because their domestic circumstances make it difficult or unsuitable to arrange for a confinement at home; others apply because some abnormality is anticipated; others again because they appreciate the many advantages of a confinement conducted in accordance with the best methods of midwifery practice. Cases of minor difficulty are fairly frequent, but the home does not profess to provide for patients who are likely to need major operative measures at the time of confinement, and such women are referred to an appropriate hospital. Patients are expected to contribute towards the cost of treatment according to their means, and only those whose income falls short of a prescribed limit are eligible for admission. The home contains accommodation for a few "ex-babies" belonging to women admitted for their confinements who cannot make proper provision for their little children during their absence from home. There is also an ante-natal clinic in the grounds, apart from the main building. The medical report by Dr. E. Collingwood Andrews shows that 264 patients were admitted during the year; half the mothers were primiparae. Two maternal deaths occurred, and of the babies 13 were still-born and 3 died shortly after birth. There were 43 abnormal labours necessitating 20 obstetrical operations, of which forceps delivery accounted for half. Induction of labour was practised in four cases—twice for contracted pelvis, once for albuminuria, and once for post-maturity.

VACCINATION PROPAGANDA.

W. M. BELTMONT.

Leicester, Nov. 17th.  
C. KILLICK MURRAY.

Sir,—I am more than surprised to find that any doctor in the present generation could, in the light of recent

research, advocate non-racination or antivaccination as a means of reducing the death rate; surely every physician

of experience knows that vaccination for any disease is only carrying out Nature's plan of curing by producing

Millard have without doubt no connexion whatsoever with

vaccination itself, but have evidently been due to carelessness in performing an otherwise simple operation. Personally I have given thousands of vaccinations against

small-pox and almost every other disease during the last thirty-six years, including vaccinating myself, and never

had a single septic complication. When we consider that millions of lives have been saved by vaccination within the

last ten years, no one in his senses would give up such a valuable means of deliverance from some of the most fatal

diseases of mankind.—I am, etc.,  
 WILLIAM VERNEY FETTERING.  
 Dublin, Nov. 1844.

**OBSERVATIONS ON CANCER.**

perhaps I may be allowed to put forward some points which are suggested by a clinical study of cases in general

practice spread over many years. To a great extent it is for the general practitioner to make his observations and

notes, and then hand them to the consultant and the pathologist.

I should like first to put down a number of suggestions as to facts to be observed, and to suggest some general and

special conditions that may be drawn from them. (Secondly, facts as here stated are put down as individual observations and no doubt are inaccurate in many points.) Secondly,

to give some possible hints as to treatment in inoperable cases.

1. Facts to be observed :

of patients I have attended with gastric cancer have had strong gastric cancer. I have been struck by the fact that the majority

(b) In cancer of the esophagus—the very common association with the excessive drinking of concentrated forms of

(c) The slow growth, or in some cases retrogression, of cartilage in the epiphyseal region, and the consequent shortening of the bones, may be due to alcohol or to excessive hot baidia.

nomia of the bowel after the making of an artificial anus, thus stopping the constant passing of irritating liquid intestinal contents over the diseased surface.

(d) The comparatively slow growth and mildness of symptoms where the cancer has a chance of growing freely in some direc-

tion, without causing excessive tension of the structures into which it grows.

and of carcinoma in old and less vigorous tissues, apart from the fact that the former grows in the mesoblast, the latter in

(5) The apparently more frequent incidence of carcinoma of the hypoblast and epiblast, and that the former is spread by the blood current, the latter by the lymphatics.

(5) A suggestion for the systematic study, and tabulation of

the results of such study, or the natural history of cancer in operable cases—the natural course or courses of the diseased

As the value of institutions of this kind is very widely recognized, some interest attaches to the financial position of the home. It appears from the balance sheet that the fund for the building amounts to something over £35,000. There is a general endowment fund of £28,274, and a special equipment fund of £1,019. The total amount entered under capital accounts is thus £64,814. From the income and expenditure account for the year ended March 31st, 1923, it appears that dividends on investments yielded £1,568, patients' payments £1,472, and pupils' payments, less lecture fees and fees returned, £313. The Home received a grant from the Ministry of Health of £1,000. Altogether the contributions received from various charitable persons towards the upkeep of beds seem to have amounted to £1,605, and of this £1,053 was allocated to the year's working, the balance of £552 being carried to reserve. It also received gifts in kind from Queen Mary's Needlework Guild estimated at £337. On the other side of the account the cost of maintenance was £3,927, and of administration, including rent and rates, £446, leaving a balance, being the excess of income over expenditure, of £1,384, or a little less than the amount received from patients' payments, which provided about a fourth of the total income.

#### INCOME TAX IN THE DOMINIONS.

A GOVERNMENT publication recently issued gives a digest of the income tax laws in force in the various British Dominions, Colonies, etc. This little volume<sup>1</sup> may be a useful book of reference for specialists in income tax work, but is hardly to be recommended for general reading. It is, however, interesting to note the manner in which certain of the Dominions have tried, and it would seem not without some success, to bring the taxation of income into closer relation with the individual's actual circumstances. This development has, in the main, proceeded along the line of giving deductions for certain expenses; for instance, in the case of the Union of South Africa the life assurance allowance was not only adopted, but extended to cover premiums paid for insurance against "sickness," while in the case of the State of Victoria allowances are made in respect of payments made to a qualified medical practitioner or any hospital, to any nurse, or to any chemist. Other deductions of general interest might be mentioned, but we have quoted the above partly because the line of recent developments in the British scheme—for example, the increased flat rate allowances for children and dependent relatives—appears to be leading to some similar forms of allowance, and partly because there is a plain and forceful argument for allowing, at any rate in the assessment of earned incomes, the deduction of medical and surgical fees and similar expenses. The argument is this: the "earner" is as much entitled to an allowance for the cost of maintaining in working order his physical or mental capacity for work as the owner of a factory is to the deduction as a working expense of the sums he spends on the repair and maintenance of his material machinery. The professional man who in the stress of work is forced to undergo medical treatment is incurring expenditure of a nature essentially similar to that incurred in taking to pieces and overhauling an overdriven motor car or lathe. We agree, of course, that the argument can easily be pushed too far; for example, we could not reasonably suggest that all expenditure incurred by a worker on rest or recreation should be allowed for in computing his income tax liability, but we consider that the argument justifies the allowance of actual medical expenditure on the Victoria model. If there were any doubt on the point a further reason could

be adduced. The importance from the standpoint of the national welfare of the general health of the community is universally recognized, and it is clear that an allowance of the nature suggested would in the first place encourage those workers who do not come within the scope of the National Health Insurance to seek medical assistance promptly, and in the second place to meet the proper financial claims of the practitioner with greater alacrity and completeness, and thereby do something towards ensuring that that assistance shall be available. A somewhat curious reference to the medical profession occurs in the law in force in the Tanganyika Territory, in the form of a complete exemption from the income tax, but as that exemption is shared by all salaried and wage-earning employees and by the recipients of profits derived from farms and plantations, the favour is not one for which the medical practitioners concerned are likely to feel any special gratitude.

#### GARDEN CITY SANITATION.

DR. M. HINDHEDE of Denmark is well known for his work on diet and his advocacy of a strictly vegetarian regimen. As an expert in drains and the commercial value of excreta he is a comparative novice, but there must be a beginning to everything, and his recent excursion into the domains of sanitation is interesting. At a lecture<sup>1</sup> given to the Danish *Hygienisk Lægeforening* he painted a vivid picture of the smallholder, allotment owner, simple-life enthusiast, the ointment of whose happiness would be perfectly pure but for one fly—the sanitary engineer. Dr. Hindhede has recently made a tour of inspection of the garden cities of England and Germany, and the garden city of Eden near Berlin is given such high praise at the cost of the garden cities of England that, if Dr. Hindhede's judgement is sound, the inhabitants of the latter must indeed be in a sad plight. His account suggests that in the English garden city large sums are spent on the house itself, a small front garden is devoted to a "pretty-pretty" effect, and the cramped back garden is an untidy wilderness, too small to make the cultivation of vegetables worth while. The value of the land having been forced up, it does not pay the tenant to rent it for the cultivation of vegetables, and for that matter it is doubtful if the English workman—as analysed by Dr. Hindhede—appreciates vegetables, what time his stomach craves bacon and eggs for breakfast. The English sanitary engineer, having to live and to justify his existence, has, according to Dr. Hindhede, hung a heavy and costly millstone of sewers round the neck of the garden citizen, with the result that houses have to be built in twos, fours, and blocks to meet the cost of sewers, the garden city becoming more and more of a city and less and less of a garden. Though he scoured the country under the auspices of the Ministry of Health, seeking colonies where sewage was used instead of being wasted, Dr. Hindhede seems to have left our shores with the sorrowful impression that we are under the heavy thumbs of our sanitarians. His impression of Eden near Berlin was very different. This community was founded more than a score of years ago, and, the land being held by the community for the good of the community, land values are not forced up, and when a settler leaves Eden his land reverts to the settlement. The infantile death rate of Eden is only 3.8 per cent., whereas, according to Dr. Hindhede, it is 5.5 per cent. in an English garden community. Though water is laid on there are no sewers in Eden, and all the excreta and waste products are returned to the soil. He estimates the annual value of a family's excreta at about £5, and agrees with the Chinese practice by which all is returned to the soil.

## SIR FREDERICK MOTT.

SIR FREDERICK MOTT finally retired from the post of pathologist to the London County Mental Hospitals and director of the laboratory at the Maudsley Hospital on October 31st. His connexion with the work of London mental hospitals began in 1895 and has continued ever since. On November 15th he was made the recipient of a very interesting presentation from those associated with him during this long period. It consisted of a Chippendale bookcase containing a complete set of the novels and poems of Mr. Thomas Hardy, and was accompanied by an album embodying a short address signed by ninety-six persons, including representatives of the medical staffs of the mental hospitals of the London County Council, of the clerical and engineering staffs of the hospitals, and of some members of the class of psychological medicine. The presentation was made at a meeting in the Council Hall by Mr. H. Keene, clerk of the Mental Hospitals Committee; Dr. Spark, the senior of the medical superintendents of the London mental hospitals, and Dr. Hubert Bond, commissioner of the Board of Control, also both spoke of the great services Sir Frederick Mott had rendered to mental pathology and medicine. Sir Frederick Mott, in acknowledging the presentation, said that although many honours had come to him he esteemed none so high as that done him by this presentation from colleagues, fellow workers, and friends. The album contained a short address in which the signatories expressed their appreciation of Sir Frederick Mott's brilliant research work, of his efforts in connexion with the establishment of the Maudsley Hospital, and of the great assistance he has afforded to workers in the field of psychological medicine. One of the members of the staff presented the following sonnet:

Who would seek Truth essays no light emprise.  
Not for his feet those paths which all may tread  
Of common use, not for his lips the bread  
Which many break, nor for his eager eyes  
Suffice that wan gleam from moon-lit skies  
Which most call Knowledge; not for him the dead  
Contentment of an oft-trod round, where sed  
By ancient Wisdom men grow custom-wise.

He looks afar, and sees a glimmering fire  
Beckon him on, a glow of dawning light  
Upon a distant peak, and through the night  
He strives, above the mist, above the mire,  
Strives in the dark, though footsteps flag and tire,  
Till, at the day, Truth breaks upon his sight.

THE AMERICAN AND THE ENGLISH COLLEGES  
OF SURGEONS.

In our issue of November 3rd (p. 835) we published an account of the Fellowship Address delivered by Sir William de Courcy Wheeler, P.R.C.S.I., on the occasion of the conferment of the honorary Fellowship of the American College of Surgeons upon himself and upon Mr. A. E. Webb-Johnson, C.B.E., D.S.O., surgeon to the Middlesex Hospital and dean of its medical school. Mr. Webb-Johnson took the opportunity of presenting to the College a specially bound copy of the volume published in 1900 for the centenary of the Royal College of Surgeons of England. In making the gift Mr. Webb-Johnson said that the volume contained the address delivered by the President, Sir William MacCormac, and a short biographical account of each of the sixty-one surgeons who had been Masters or Presidents of the College during the hundred years of its existence. The copy now presented was of special interest, for it contained an inscription showing that it was presented in 1901 by Sir William MacCormac to Mr. Stephen Paget, the only one of Sir James Paget's sons to follow a surgical career. Of the next generation of the Paget family Richard James Paget, one of the sons of the

Bishop of Oxford, was the only one to choose medicine as his profession, and the volume was presented to him by Stephen Paget in 1907. Richard Paget did not continue his medical studies, and had given the book to Mr. Webb-Johnson in 1910. With these inscriptions recording the history of the copy the donor felt that it should find a resting place in some permanent institution rather than run the risk of being dispersed with the books of an individual owner on the breaking up of his library. He asked the American College of Surgeons to accept it as a token of the good fellowship which has always existed and will ever continue to exist between British and American surgeons.

## THE AUSTRALASIAN MEDICAL CONGRESS.

THE President of the British Medical Association, Mr. C. P. Childe, sent the following cable on November 9th to Mr. G. A. Syme, President of the Australasian Medical Congress at Melbourne:

"Hearty congratulations from parent body to First Australasian Medical Congress held under auspices of Association. Best wishes for successful meeting. Sir William MacEwen will tell how proud we are of this renewed evidence of strength of Association in Australasia.

"CHILDE, President."

On the afternoon of Tuesday, November 27th, at 5.30 o'clock, a combined meeting of the Medical and Surgical Sections of the Royal Society of Medicine will be held in the Barnes Hall at 1, Wimpole Street, W.1, to discuss the surgical treatment of pulmonary tuberculosis. The discussion will be opened by Professor Bull of Christiania, who is making a special visit to this country for the purpose of this meeting. All members of the profession who are interested in this important subject, whether Fellows of the Society or not, are cordially invited to attend the meeting.

THE discussion on the comparative value of cocaine substitutes, arranged by the Sections of Surgery, Ophthalmology, Otology, Laryngology, Odontology, and Anaesthetics of the Royal Society of Medicine, will be held on Friday, December 7th. It will be opened at 8.30 p.m. by Dr. Patrick Watson-Williams of Bristol.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

PARLIAMENT was dissolved on November 16th.

## The Capitation Fee: Court of Inquiry.

LIEUT.-COLONEL NALL, on November 15th, asked the Minister of Health whether he had received an answer to the final offer he made to the panel practitioners regarding their terms of service after January 1st, and if so what action he proposed to take. Sir W. Joynson-Hicks: Yes, sir, my offer was accepted by a unanimous resolution of the Conference of Panel Committees held yesterday, the alternative being chosen of a Court of Inquiry to investigate and make recommendations as to the capitation fee properly payable as from January 1st. I am taking steps to set up the Court as quickly as possible. I understand the resignations will be withdrawn.

Mr. Rhys Davies asked whether the Minister would state where he was going to find the money to pay the increase from 7s. 3d. to 8s. 6d. Would he consult the Approved Societies on this question, and at once call together his own Consultative Council to find out what they thought? Sir W. Joynson-Hicks: The question whether anything will have to be paid to the doctors above 7s. 3d. is a matter for the Court of Inquiry. There is no need for me to consider finding any money until the Court has arrived at a decision. I shall be

A Tribute by Sir Clifford Alberts, K.C.B., P.C.

as a surgeon, Leary was both dexterous and wise. His hands were delicate, and his touch sensitive. As he began to operate, his features, at other times so mobile, set into an expression of calm resolution; and whatsoever crosses or sorrows might be in store for him, I, who was often present, never saw him perturbed; if necessary his plans would be quickly changed for the best. Throughout all Leary's work, his social life, and his public engagements there shone the light of a nature of rare beauty and charm. He was one of those who carried into maturity and old age the blithe generous enthusiasms of youth; a childlike frankness, unselfishness and sincerity. His first wife was a great sufferer for some years before her death; long years during which his friends saw with anxiety his devotion and utter broken nights at a dinner table.

were dragged about in litter with their necks fixed in yokes. Thus the disease was left for the most part to incase, propagate, break into abscess, and damage the skin on which cure largely depended. We had at first only the worst cases to deal with; neither doctor nor patient would agree to the early surgical interference by which we desired to secure a linear scar so placed as to be drawn up invisibly under the jaw. By dealing with these severe cases, however, we learnt many of the tricks of the dissection. Well I remember, in our early attempts, the case of one greater Yorkshire houses upon whose daughter of one of the tall, handsome, and courageous daughter of one of the tall, handsome, and courageous

scrofula I feel had to operate, for more or less, including the excision of old pockmarked scars, fourteen times; and with, at last, satisfactory results. Among other devices we learnt the drill, even in early cases, of over-looking small abs-nodules, leading to rotting of large operation caught on, and it will hold its way until by radium, perhaps, and still better by preservation, it become unnecessary. This was our chief work in common; but during my residence in Leeds we travelled together over many a field in mutual counsel and help.

two were examined at later dates and both remained free from discharge, one after ten weeks and the other after four months. Three cases in which a slight discharge persisted were afterwards treated by zinc or copper ions and the discharge disappeared. These cases were seen again after two, three, and six months respectively, and no discharge was visible. In the remaining six cases the patients said that the discharge had diminished. In these the discharge was not purulent in appearance, and in one it was clear and resembled mucus. In one of the two cases in which gonococci were not found before the diathermy the discharge disappeared after the treatment; the patient was told to report again but did not do so. The other case could not complete the treatment as she had to leave London; her doctor reported that the discharge was "much less." The patient from whom the gonococci could not be made to disappear was probably reinfected as her husband also had gonorrhoea and was under treatment at the centre.

The question whether complete cure of gonococcal cervicitis or urethritis has been obtained cannot be answered by the absence of gonococci from the discharge. Complete subsidence of discharge is in its favour. Often, however, some discharge continues, and the question will arise in such cases whether the discharge is pathological. A discharge of pure mucus is not evidence of gonococcal infection. If, however, pus is present in the discharge it must be considered as pathological. A point in the treatment will often be reached in which although the discharge is mainly mucus there are still present small numbers of leucocytes. After ionization and diathermy in which sloughing has taken place leucocytes will be present as the result of the formation of granulations. Often, on the cessation of treatment, these will disappear and the discharge will finally clear up after a short time without further treatment. It is to be remembered that these treatments to the cervix *tend to maintain* this muco-purulent discharge. It becomes therefore a matter of judgement founded on experience when the treatments should be left off in the expectation that the discharge will eventually cease.

#### *Treatment of Gonococcal Prostatitis by Diathermy.*

At present we have not obtained sufficient evidence to enable us to make a definite conclusion on the action of diathermy on gonococcal prostatitis. Our results so far seem to show that the new treatment possesses therapeutic action in this disease. We treated one of our cases of prostatitis by applying diathermy to the prostate only, and obtained the effects already mentioned—namely, abolition of pain, reduction of swelling, and increase of movement. We also noted the disappearance of pain and tenderness from the epididymis in a case of gonococcal infection of this part after application of diathermy to the prostate only. The following case also is suggestive. The patient gave a history of gonorrhoea. In his perineum there was a fistula leading to his urethra immediately behind a stricture of the passage mentioned. He complained of severe pain in the right lower limb. There was tenderness on pressure over the back of the thigh and flexion of the hip caused extreme pain. It was decided to apply diathermy to the prostate only. Complete and permanent relief of pain was produced, and the only symptom which remained was some discomfort on stooping with the knees extended.

It has already been mentioned that some of the cases of arthritis did not obtain relief until the urethra and prostate were also subjected to diathermy. In all these cases, save that described above, both prostate and urethra were treated simultaneously. We are therefore unable to state the region on which the diathermy exerted its therapeutic action—whether the urethra or prostate or both. Further light on this question would be thrown by the application of diathermy to cases in which only the anterior urethra was infected and to others in which the clinical evidence pointed to subsidence of infection from the anterior urethra with persistence in the prostate. This investigation is at present occupying our attention.

## DIATHERMY FOR MALIGNANT DISEASE OF THE MOUTH, PHARYNX, AND NOSE.

WITH NOTES ON SEVENTEEN SUCCESSFUL CASES.

BY

NORMAN PATTERSON, M.B., CH.B. EDIN.,  
F.R.C.S. ENG.,

SURGEON, THROAT AND EAR DEPARTMENT, LONDON HOSPITAL.

For the last eight years I have been employing diathermy in the treatment of carcinoma affecting the mouth and pharynx. Unfortunately, the great majority of the patients treated were suffering from advanced disease; this was true of all the early cases, and of nearly all those treated in hospital. A very considerable number of patients were suffering from secondary deposits in the glands on one or both sides of the neck, and in some cases the glandular involvement was extensive. Cutting operations of magnitude had, therefore, frequently to be carried out in the neck; diathermy is rarely, if ever, of any use in dealing with the malignant extensions in the neck. Faulty technique and the too timid use of the diathermy electrode accounted for some of the failures in the earlier series of cases. Owing to the great size or unfavourable position of the growth, or the general cachectic condition of the patient, many of the cases dealt with would now be deemed unsuitable for any sort of treatment. Haemorrhage during the separation of the sloughs was a not infrequent occurrence. Since I have adopted ligation of the main vessel or vessels supplying the part in cases requiring extensive diathermy, or in patients with thickened arteries and high blood pressure, severe haemorrhage has not been met with.

When the growth is small, superficial, and situated some distance from important and vital structures, and when the glands are free from involvement, or only slightly invaded, there is an excellent chance of a complete and lasting cure. My experience is that, if local recurrence is going to take place, it will generally happen during the first six months. This, of course, does not apply to recurrences in the neck. When the primary growth is very extensive, deeply rooted, and situated in a locality unfavourable to its free destruction, and more especially when the secondary deposits in the neck are massive or fixed, there is little likelihood of effecting a cure, and there may be great risk in subjecting the patient to operation. However, most of the cases recorded in this article were described by others as "inoperable," and some of them were very extensive; it is difficult, therefore, to draw the line between cases which should be subjected to treatment and those which should be left alone. Much depends on the general condition of the patient and the special experience of the surgeon. Every practitioner should be alive to the grave significance of an ulcer or indurated area occurring in the tongue, mouth, or pharynx of a patient over middle age. The condition rarely proves to be simple, or due to any other cause than malignant disease. It is well, therefore, to regard every doubtful case as one of cancer until it is proved to be due to some other cause. To the practised observer the diagnosis of epithelioma is generally easy. Over and over again the author has seen patients who have been diagnosed as suffering from "septic ulcer," "cyst," "gumma," when the real trouble was epithelioma. Many cases of supposed syphilis are repeatedly injected with salvarsan or soaked with iodides. It is important to remember that a great many patients with buccal or pharyngeal cancer will give a positive Wassermann reaction.

In the majority of cases the growth is visible on ordinary inspection—it is generally best to use reflected light. If it is situated at the base of the tongue, low down in the pharynx, or in the neighbourhood of the larynx, a laryngeal mirror will be required for its inspection. In nearly all cases palpation with the finger is possible, and it should never be omitted, as the cartilaginous hardness of an epithelioma is one of its most characteristic features.

Microscopic examination of a fragment of the tumour

which the diagnosis. There is one objection to this method—namely, that even such a small operation is followed by more rapid advance of the growth, and this especially the case if some of the surrounding healthy tissue is removed at the same time. Before removing a tumor for microscopic examination, consent should, therefore, be obtained for an early operation, should such an operation be found to be necessary.

So far the only treatment of cancer which has stood the test of time is that which aims at the total removal or destruction of the tumor and its extensions. The writer comes to the conclusion, after considerable experience, that in cancerous growths situated in the pharynx and in the primary growths are likely to be inoperable better than by a cutting operation. He stated (Lancet), on this reason for this opinion, which he has had no use since to modify. Many brilliant successes would be obtained if the disease could only be diagnosed and treated in its early stage.

The glands have not been removed in every case; this is due to the fact that consent has not always been obtained. Removal of glands (and this generally means thorough clearance of both anterior and posterior triangles of the neck, and the dissection) should be carried out even when enlarged glands can be discovered on palpation. In one of the author's cases—not recorded in this series because he is a recurrence—a man suffering from a small epithelioma of the larynx, and just extending on to the soft palate, was treated by diathermy. There was no enlargement of the glands, but the patient was urged to have the dissection of the neck cleared out on both sides. He absolutely refused. Four years later malignant glands have developed on both sides of the neck; the region of the palate has remained perfectly healthy. It is generally advisable to destroy the growth in the first instance, and subsequently to remove the glands. Occasionally the two operations can be carried out at the same sitting. If the surgeon is in doubt whether or not he can make a thorough clearance of the neck, then the gland operation should be dealt with it is little use applying diathermy to the primary tumor, except as a palliative measure. It is sometimes advisable to operate on the glands in the first instance, and to deal subsequently with the primary tumor, as consent for the neck operation may be difficult to obtain after the growth has been destroyed. Before commencing treatment it is well to try and obtain consent for two or three operations, and to impress on the patient the importance of the removal of glands. If the dissection is not approached or invades the fascial planes of the neck—and this is most likely to occur in cancer of the floor of the mouth—a clear interval of a fortnight or three weeks should be allowed between the destruction of the primary growth by diathermy and the neck operation. If this rule is not observed alarming sepsis may occur in the neck, which may lead to a fatal issue. Preliminary ligature of the external carotid should be adopted, as stated above, when secondary hemorrhage is to be feared.

The following cases have been successfully treated. In some of these it might almost be stated that a cure has been effected; in most of them it is to be hoped that the disease will not recur.

# Case 7.

A man complained of sore throat, and on examination there was discovered an extensive epithelioma of the right tonsil and right side of the tongue and of the floor of the mouth. This was treated by diathermy, and the patient went on well for a time. Later, however, he returned to hospital with a carcinoma-like tumor involving the right side of the tongue and the right side of the mouth, and there was a large, hard mass in the right submaxillary region. The tumor in the mouth was subjected to vigorous diathermy, and the mass in the neck was removed by dissection. The patient, nearly eight years later, is actively engaged as a tram conductor and at present there is no sign of growth.

# Case 8.

An elderly lady was found to be suffering from endopharyngeal growth at the base of the tongue. With the aid of suspension laryngoscopy the growth was removed by diathermy (excision method). There was no recurrence six years after operation.

A man, aged 52, complained of soreness of the floor of the mouth and a lump at the right side of the jaw, of two months' duration. On examination a carcinoma of the middle of the floor of the mouth was found; the tongue was freely movable, and there was an enlarged hard gland in the right submaxillary region; the glands on the left side were not enlarged. The growth was freely destroyed by diathermy, and a fortnight later the glands were removed in the usual way. There was no recurrence more than six years after.

# Case 9.

A woman, aged 58, presented a cauliflower-like growth (epithelioma) on the right side of the hard palate, and on transillumination the right alveolar was dark. The upper jaw was resected, and three weeks later the cavity was thoroughly subjected to diathermy. The patient went on well for a year and ten months, when she reappeared with a small nodule in the scar, which was destroyed by diathermy. Six months later she came to hospital with a large mass in the upper part of the neck, which was removed, together with the tonsil and glands in both anterior and posterior triangles, the internal jugular vein, and the upper portion of the sternomastoid muscle. She is well six years and three months after the original operation.

# Case 10.

A man, aged 55, complained of soreness of the throat, of seven weeks' duration; there were enlarged glands on the left side of the neck. An epithelioma of the posterior part of the tongue on the left side was found, invading the anterior pillar of the fauces and the tonsil. The growth was removed by diathermy, and subsequently the glands on the left side of the neck were removed. There was no recurrence five years and three months after operation.

# Case 11.

A man, aged 57, complained of pain on swallowing for several months; he was an excessive smoker, but a total abstainer. Examination showed a large epithelioma of the right tonsil and palate, which was removed by diathermy. A year later the glands on the right side of the neck were thoroughly removed. There was no recurrence four years and five months after operation.

# Case 12.

A man, aged 56, had a small superficially placed epithelioma of the left tonsil and anterior pillar; there were no enlarged glands. The growth was thoroughly destroyed by diathermy. Three months later a hard gland was discovered over the bifurcation of the left carotid. The anterior triangle was dissected, and three months later, a small gland being felt in the left posterior triangle, this region was cleared. There was no recurrence over three years after the first operation.

# Case 13.

A man, aged 61, had noticed a small lump on the left side of his tongue for four months. Examination showed an epithelioma of the tongue and floor of the mouth; no glands were palpable. Diathermy was employed, and the tongue was divided down the centre and cut across well behind the growth. There was no recurrence two years and three months after operation.

# Case 14.

The patient, a man, had noticed a hard lump on the right side of the tongue for two or three months. On examination an epithelioma of the tongue and floor of the mouth was found; no glands were palpable. The growth was removed by diathermy, and a fortnight later the anterior triangle of the right side was cleared. Six weeks later the glands were removed from the left side of the neck. There was no recurrence two years after diathermy.

# Case 15.

A man, aged 72, had noticed "a little bladder" on the roof of the mouth for six weeks. He was a moderate smoker (wooden pipe). An epithelioma of the roof of the mouth was found and removed. There was no recurrence one year and ten months after operation.

He was the most delightful old man I have known; and I thoroughly enjoyed my visits to him, and always learnt much from them, as his experience and knowledge were prodigious. I think, perhaps, his greatest charm was his intense and kindly interest in other people and the complete absence of the usual self-absorption of extreme age. Up to three weeks ago he still took the greatest interest in politics and the affairs of the day and the progress of medicine and science; and he would quote passages from Latin and Greek with the relish of a "true classic"—and which, I am ashamed to confess, I professed to recognize. I perceived that the ideal of his life had been a very high one and that his goal had been "discovering the truth and perfecting his work." In his frail and very slight body there was a great and courageous soul—three years ago he faced with unwavering courage and calmness a major operation, which Sir Berkeley Moynihan performed on him with the most brilliant results, that added three more happy years to his life.

The passing of his great, gentle, and courtly spirit causes me, and all who knew him, a very real sorrow, and we feel a great pang of regret at having to part with "Dear Old Teale," as we all instinctively called him.

[A detailed account of Mr. Teale's career was published last week, page 918.]

#### FRANK STANLEY TINKER, M.B., B.Ch., CAMB.

THE death occurred on November 11th of Dr. Stanley Tinker, at the age of 36 years, after a long illness. He was educated at Liverpool College, at Repton, and at Pembroke College, Cambridge, where he graduated B.A. in the Natural Sciences Tripos of 1908. After obtaining the M.R.C.S. and L.R.C.P. diplomas in 1911, and holding various house appointments at Liverpool Royal Infirmary, he showed some early signs of pulmonary tubercle, on account of which he went to Arosa, Switzerland, in the spring of 1913. For two years or more he underwent sanatorium treatment, utilizing the time to make himself familiar with both the clinical and the laboratory sides of the work. In 1914 he returned to England to take his Cambridge medical degrees, and next year became in session school medical officer and tuberculosis officer for two of the divisions of Surrey, and medical superintendent of Crooksbury Sanatorium, Farnham. His interest in the provision of municipal workshops for tuberculous patients resulted in a scheme which he published for the post-sanatorium employment of the consumptive ex-soldier, and no doubt led to his appointment in charge of Barrowmore Hall Tuberculosis Colony, near Chester, where he proved himself to be an able administrator. Here he had a relapse which ultimately proved fatal. He had been an active member of the editorial board of *Tubercle*, and was responsible for a translation of Cornet's monograph on miliary tuberculosis. His death removes one whose combination of administrative and clinical ability was producing work of real value. Stanley Tinker was an only son; he leaves a widowed mother, a widow, and two young children.

Dr. EDWIN AUGUSTUS WADESON died after a short illness on November 13th, at South View, Sedbergh, Yorkshire, where he was a well known and respected local practitioner. From Sedbergh school he went up to St. John's, Cambridge, and afterwards became a medical student at the London Hospital. He graduated M.B., B.Ch. in 1890. He commenced practice in Sedbergh thirty-four years ago, and for eighteen years was medical officer and public vaccinator for Dent. By dint of unsparing zeal and untiring devotion to his practice, he had won such a place amongst the people of the countryside as is attained by few. A man of ability, but unassuming and plain, he had given his life entirely to the welfare of his people, and died in harness, lamented by all who knew him. To his widow and daughter the deepest sympathy will be extended.

By the death on November 11th of Dr. CHARLES RICHARDSON in his 81st year, Leeds loses one of its oldest medical practitioners. Dr. Richardson took the diploma of M.R.C.S. Eng. in 1867, and subsequently practised in Leeds up till about ten weeks ago, when he underwent a severe operation. He was an ex-president of the Leeds

and West Riding Medico-Chirurgical Society, and late surgeon major 2nd West Riding Royal Engineers, having been awarded the V.D. He took a keen interest in all forms of recreation. He was a man of outstanding personality, who gained the confidence of his patients and colleagues. He is survived by a son in South Africa, who is a member of the medical profession, and three daughters.

Dr. HUBERT H. THOMAS of Brynhyfryd died on November 1st, aged 53. He was the son of the late Dr. William Thomas, for many years assistant overseer for Swansea, and received his medical education at Charing Cross Hospital. He took the diplomas of L.S.A. in 1895, and the Scottish Triple qualifications in the following year. On returning to Swansea he assisted in the practice of his uncle, the late Dr. Howel Thomas, J.P., and subsequently undertook what became later a large practice at Brynhyfryd. He was medical officer at the Cwmfelin works, where he was held in high esteem by the workpeople. He took great interest in ambulance work; he founded the Brynhyfryd division, and was subcommissioner of the priory of Wales. Dr. Thomas was a keen sportsman and at one time captain of the London Welsh Rugby team, and at the time of his death was captain of the Manselton cricket club. He was a member of the Swansea Division of the British Medical Association, and a justice of the peace. At the commencement of business at the Swansea police court on the day of his death a vote of condolence with the relatives of the deceased was passed. At the funeral on November 5th six staff officers of the Order of St. John acted as pall bearers, and the medical profession was well represented, Dr. Horatio Rawlings acting as the representative of the British Medical Association.

The death is announced of Dr. BOULLOCHE, a well known Paris paediatrist.

Dr. GENARO SISTO, professor of pediatrics in the University of Montevideo, has recently died. His essay on constant crying as a sign of congenital syphilis in infancy, sometimes known as Sisto's sign, was awarded the Peiron prize of the Paris Académie de Médecine.

## Universities and Colleges.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

#### MEETING OF COUNCIL.

AN ordinary meeting of the Council was held on November 8th, when Sir JOHN BLAND-SUTTON, President, was in the chair.

Diplomas of membership were granted to 170 candidates. The diploma of Fellowship was granted to Sybil Grace Mocatta. Mr. C. H. Fagge was appointed to represent the College on the General Council of the Fellowship of Medicine, and Mr. Raymond Johnson was appointed to represent the College on the Managing Committee of the Schiff Home of Recovery.

It was reported that five lectures on the influence of environment on the life of bacteria would be delivered in the lecture theatre of the College by Mr. F. W. Twort, superintendent of the Brown Animal Sanatory Institution, on December 11th, 13th, 17th, 18th, and 19th, at 4 p.m.

The PRESIDENT reported that the vacancy on the Court of Examiners occasioned by the expiration of Mr. Warren Low's term of office would be filled at the ordinary council meeting on December 13th. Mr. Low is eligible for re-election.

#### ANNUAL MEETING OF FELLOWS AND MEMBERS.

The annual meeting of Fellows and Members of the Royal College of Surgeons of England took place on November 15th, under the presidency of Sir JOHN BLAND-SUTTON.

The annual report (BRITISH MEDICAL JOURNAL, October 6th, 1923, p. 636) was presented, and questions were invited. Mr. C. E. WALLIS asked for a statement of the attendances at museum demonstrations, and Dr. F. W. COLLINGWOOD inquired how many Fellows had returned their votes in the recent election to Council. The PRESIDENT replied that a careful record was formerly kept of museum attendances, but it had been allowed to fall into abeyance; in future it would be restored. The number of Fellows voting in the election to Council was 1,052.

Dr. EDWIN T. H. NASH was in charge of a resolution affirming the desirability of admitting Members to direct

representation on the Council of the College, and requesting the President and Council to consider some means whereby Members in general practice might be represented on the Council. After paying a tribute to the late Sir William Thorburn, Dr. Nash said that his position in moving this resolution was not provocative but pacific. At the same time he wished to reply to some of the arguments which the then President, Sir Anthony Bowlby, had advanced at the last annual meeting. Sir Anthony Bowlby had said that during the war, when he met many Members of the College on service, none of them had complained to him of disabilities. But that was not an occasion when men would be likely to discuss their civil grievances, and in any case it was only negative evidence. Again, it was stated by Sir Anthony Bowlby that there were Fellows on the Council who could be said to represent general practice; the speaker knew of no one on the Council who was acquainted in any close degree with the difficulties of the general practitioner. A further remark of Sir Anthony Bowlby was that the Society of Members did not embrace the 16,000 Members of the College. That was true, but it could claim to represent the man who had nothing but what he called his "Conjoint" when he compared himself in the open market with those who had a university degree. There was a feeling that the man who had only the "Conjoint" belonged to "the lesser breeds without the law," but a very large majority of "Conjoint" men were the victims of circumstances, their parents having either been ignorant of the medical portal or with insufficient means to afford the extra year to take either the London degree or the Fellowship. The speaker dealt with some of the difficulties of the men entering medical practice in London as compared with the provincial graduates who had, as it were, the university on their doorsteps. He was sure that those who were on the Council of the College did not appreciate the difficulties which the men who had qualified under its guidance had to suffer, and he suggested that six members of the Council should meet around a table six Members of the College who were only "Conjoint" men and talk over the position. He had enough faith in the general goodwill and common sense to promise that, if the President would agree to that suggestion, he would at once withdraw his resolution. The President giving no sign, Dr. Nash proposed the resolution as it stood.

Dr. REDMOND ROCHE seconded, and asked whether it was reasonable that there should be an electorate of 1,600 in a corporate body of 18,000. It was true that some Fellows were in general practice, but theirs was really a special type of practice, and they could not be said to represent the average general practitioner. Even so, no Fellow engaged in general practice had ever been elected to the Council of the College, nor was it likely that he would be in view of the great numbers of consulting surgeons who were Fellows. What steps had the Council taken to elicit the views of its present electorate on the admission of Members to the franchise? Sir Anthony Bowlby had said that a referendum had been taken on two previous occasions, but those two occasions were as far back as 1886 and 1897. In reviewing the past struggles it was interesting to recall the fact in this centenary year of the *Lancet* that the founder of that journal evoked the wrath of the authorities of the College by holding an unauthorized meeting, and, the police being summoned, he spent several hours, if not the whole night, in Bow Street police station! Quite recently the Society of Members had issued a questionnaire to all Fellows, to which a surprisingly large number had replied, and 73 per cent. of those replying had stated themselves to be in favour of the principle that Members should be granted some representation on the Council, and about half of these had testified to their willingness to assist the efforts of the society in this direction. Sir Anthony Bowlby had spoken disparagingly of the membership of the society, but of course, as in all such bodies, the society included, not all those affected, but the more energetic and zealous men. During the last year it had circularized all the Members of the College, and only one man had written to say that he felt no particular interest in the matter, while hundreds of Members and many Fellows had since joined the society.

Dr. NASH moved that the question be now put, and Mr. DENNIS VINNAGE seconded, their object being to prevent any possible disturbance of the peaceful atmosphere by a prolonged discussion, but the point was not taken, and the discussion was continued by Dr. F. G. LLOYD, Dr. F. W. COLLINGWOOD, Dr. ARTHUR HAYDON, and others. The President then put the original resolution and declared it carried unanimously.

Dr. H. M. STRATFORD moved to request the President to make a statement to the meeting as to the difficulties, legal or otherwise, which in the opinion of the Council prevented it from assenting to some form of direct representation of Members. Dr. CHARLES HAYWARD seconded, and said that the real trouble was the charter of 1843, in which the rights

of Members were "jumped." During the past year 50 new Fellows and 632 Members had come in, so that the constituency which had no vote was increasing at twelve times the rate of the constituency which had a vote. The finances of the College derived four times as much support from the Members as from the Fellows, yet it was only the Fellows who had a voice in the management.

This motion also was carried unanimously.

The President said that this was the first time he had had the privilege of presiding at the annual meeting, and he had paid very careful attention to the answer he should give. The previous year Sir Anthony Bowlby had made a clear statement of the views of the Council in regard to a similar resolution, and with this statement he associated himself. Under the charter of the College the Fellows were the electorate. Every Fellow was eligible to stand for the Council, and any Member could become a Fellow by passing the required examination. The Fellows of the College were engaged in all kinds of practice, special and general, and Fellows in general practice had served on the Council. Although the Members numbered 16,000 it had always been difficult to get a quorum of thirty—2 per 1,000—at the annual meeting, and this might be taken as an indication that Members as a whole had little cause for complaint so far as the management of the College was concerned. At the last election to the Council four-fifths of the electorate voted, showing that the Fellows took an interest in the affairs of the College. The College was incorporated for the promotion of the art and science of surgery. Its principal duty was to take care that those who desired to become Members should be properly educated and trained in that art and science. The College contained a library and other facilities for the use of Members and Fellows alike. The Membership of the College was in great demand, and its diploma as a standard of ability was recognized throughout the world. If Members had any considerable grievances medical men and women would not be so keen to obtain this diploma. The outstanding position of the College was in a great measure due to the constitutional provisions of the charter, and the Council regarded the changes advocated by some Members as arising from a mistaken view of the functions of the College.

We have received the following letter with reference to the President's speech:

SIR,—Will you favour me with space to reply to the remarks of the President of the College at the close of the annual meeting? The Members had not an opportunity of answering then, and Sir John Bland-Sutton did not reply to the suggestions made nor to the points then brought forward for the first time. Instead he read out a previously prepared statement. The President told us if we wanted a vote for the Council all that was necessary was to become Fellows! He lauded the status of the College, its library, and museum. The mouse in the trap is not particularly interested in being told of the excellent quality of the cheese that has attracted him. He is likely, if he can—by wireless or otherwise—to tell his own little mice and other mice outside not to follow him. The President appears to give all the credit to the Charter of 1843 for the high position of the College to-day. One seems to have heard of great surgeons of the College before that date, and surely John Hunter deserves some credit for the fame of the museum. Is there not some evidence of myopic vision in the prospect and retrospect of the Council of the College? The Member is "the foot" in the shoe, and he knows when and where it pinches. All he asks is that his "head" (the Council) should appreciate, and if possible relieve, his discomfort. That is not possible if the lines of communication—the nerves—between the "foot" and "head" are disconnected as they are at present. There is no liaison officer between the Members and the Council, no way by which the Council can now get first-hand knowledge of the Members' views. This is the essence of the Members' difficulty and claim.

From the President's speech one would infer that the College is only concerned with the production, on eugenic lines, of a perfect surgical baby. When he is born his Alma Mater leaves him on the (outer) steps of the College for any foster-mother to protect—for example, the British Medical Association. This appears to be their conception of parental responsibility. If such is the sole function of the College, as Sir John Bland-Sutton appears to claim, why does it speak in the name of its 18,000 Members, without first ascertaining their views, on matters of medical policy when consulted by the Government, etc.? The Council last year made a point that in conceding the Members' claim it would be acting at variance to the views of its electorate of 1,700 Fellows. Can it be believed that the last occasion it consulted the Fellows on this question was in January, 1897—nearly twenty-seven years ago! The Society of Members sent a questionnaire post-card to the Fellows some

Norman Kerr Memorial Lecture

103

DRUG ADDICTION.

DELIVERED BEFORE THE SOCIETY FOR THE STUDY OF

INTEMPERITY, OCTOBER 9TH, 1923,

AT

SIR W. H. WILCOX, K.C.L.E., C.B., C.M.G.,

M.D., F.R.C.P.,

PHYSICIAN TO ST. MARK'S HOSPITAL; MEDICAL ADVISER TO

THE HOME OFFICE.

DR. NORMAN KERR, in memory of whom we are assembled here to-day, devoted his life's work to the study of

incontinence, and it may be truly said of him as of other good and great men, "Their work lives after them."

This society, of which he in 1884 was the illustrious founder, has steadily and perseveringly and with increasing influence and power followed the principles for which

it was founded—"To investigate the various causes of incontinence and to educate the professional and public mind."

The Society for the Study of Incontinence is of itself a fitting monument to the memory of Norman Kerr. His devotion to the subject he constantly had at heart, and his persevering efforts had a great share in the passing of the

Acts for the reform of incontinents from 1879 to 1888. His leisure time was spent in compiling carefully written works

on the subject dear to him, and these remain with us as examples of the humanity and scientific spirit with which

the study of incontinence of all kinds should be approached at the present day.

In all his writings Norman Kerr insisted on regarding incontinence as a disease rather than a willful vice. He

pointed out that alcoholism and drunkenness were only one variety of the disease "incontinence," and to avoid confusion

suggested as an alternative term for incontinence, "narcotism," which is literally a torpor (torpor, torpor).

or in other words an overpowering impulse for narcotism by any intoxicating or anæsthetic substance. The disease

of incontinence or narcotism he regarded as a true intoxication mania, the diseased intellect often utterly abhorring to

the liquor (or drug) which he would barter his salvation to procure.

DRUG ADDICTION.

It is impossible to name with limitation the drugs which

may give rise to an addiction habit, because any drug having an intoxicating action on the cerebrum may give

rise to addiction, and new drugs of organic composition being daily added to our pharmacological armamen-

tarium, the effect of which as regards addiction is at present unknown. In this respect a word of caution is

necessary. New organic compounds are being constantly discovered for which it is claimed that they do not cause

addiction and that they are in every way capable of replacing those drugs, such as cocaine, morphine, and

barbituric acid, which are dreaded for their tendency to lead to the drug habit. The claim that a new drug is not likely to

lead to "addiction habit" requires the most careful and extended trial both experimentally and therapeutically

before it can be admitted. To quote one well known example—novocain. This has

been successfully used in certain operations as a substitute for cocaine, but it does not have the anæsthetic effect on

muscular membranes characteristic of cocaine, and is used

solely for infiltration of the subcutaneous tissues; for this purpose it is an admirable anæsthetic. Novocain is not

known to give rise to "addiction," but has been almost

universally used by surgeons. Prescriptions for it have not

as yet been the opportunity of testing the addiction pro-

portunities as has been the case with cocaine. It is possible

that the hypodermic administration of novocain might, if

continued, give rise to addiction. One must keep an

open mind with regard to addiction properties of new

drugs. I shall therefore restrict my remarks to drugs

which are well known to have given rise to addiction.

These are:

Opium and its alkaloids, morphine and heroin. ? Dionine

and codeine, cocaine.

Diethyl barbitalum acid and other allyl, aryl, or metallic

derivatives of barbitalum acid, such as veronal, medonal,

propional, dial, luminal, etc.

Chloral.

Cannabimide.

Supponal and its homologues, trional and tetronal.

Chloroform and ether.

Faraldehyde.

The most important of the drugs of addiction are: opium,

heroin, and heroin; cocaine; the veronal group; chloral;

Let us consider first drug addiction in relation to those

drugs included under the Dangerous Drugs Regulations—

namely, opium, morphine, heroin, cocaine, and their deri-

vatives—since in the vast majority of cases it is these

drugs which are responsible for addiction and which are a

menace to the national health and well-being.

ETIOLOGICAL FACTORS: STATISTICS.

Is drug addiction common in this country? It is im-

possible to answer this question with mathematical accu-

racy, for no statistics are available. Speaking from personal

experience, and a close study of toxicological medicine ex-

tending over the last twenty years, I am of opinion that

drug addiction is rare in this country amongst the working

and professional classes. Persons of this class, we may call

them "the citizen class," become victims of the drug

habit often from taking the drug in medical prescriptions

and through no fault of their own. They are honest in

their intentions and in their lives, and find themselves the

victims of a terrible habit—or, as we would better term it,

they become afflicted with "an addiction disease." They

conceal their plight for a time, but ultimately realize that

disaster is imminent, and then they seek medical advice.

They wander in their distress from one doctor to another,

vainly seeking a cure, and their trouble becomes known

to many. There is thus a tendency to exaggerate the num-

ber of drug victims of this type. I believe the number

in this country to be very small.

There is another class of persons in whom the drug habit

is very common. It includes those who devote their

lives to so-called pleasure seeking and the search for new

excitements and sensations. In American literature they

are described as the "Underworld." They might be

termed the "Vicious Group," the addiction arising either

purely as a means of endeavouring to induce pleasurable

sensations or as the result of evil association with addicts,

leading to the corruption of good habits. Amongst the

drugs usually employed, either hypodermically or as snuff,

the "vicious group" of drugs addicts is to be found in

London and our great cities. Fortunately it is a small

group, and one whose influence is not extensive. Addic-

tion of the "vicious" type is a canker to be stamped out,

though one must admit that this form of drug addiction

is not such a serious menace to the national well-being as

that affecting the citizen class.

INTERMEDIATE CAUSATION OF DRUG ADDICTION.

The commonest cause of drug addiction in this country,

if we exclude the "vicious group," is undoubtedly the

prescription of the drug for medical purposes.

The Relief of Pain.

It is common for morphine and heroin to be prescribed

hypodermically for this purpose. The use of these drugs

is necessary in certain cases. It may be necessary, in order

to alleviate pain and promote sleep, for a hypodermic

injection of morphine or heroin to be prescribed on one or

two nights after an operation, particularly in abdominal

cases. Too much care cannot be exercised by surgeons in

this respect, and instances have occurred where harm has

been done or a drug addiction developed.

Recently there has been under my care a most serious case of

heroin habit in a patient who has done everything possible to

overcome the addiction. This patient, seven years ago, was given

[3283]

months ago. The results are still coming in from abroad, but a surprisingly large number of Fellows courteously replied, and over 73 per cent. of the replies were in favour of the Members' claim.

The Fellows were praised by the President for showing great interest in their College because less than two-thirds of them voted (by post) for the Council; while the Members were said to be apathetic because, though scattered over England and the Colonies, busy men in general practice, they did not in larger numbers attend the annual meeting to vote *in person* for their claim. Can it be wondered that they are not eager to come when the only result of their exertions is to receive from the Council a chilling *non possumus*? Is there logic or fairness or even a common denominator in this comparison? Would it not be more reasonable for the Council, if they have any real doubt as to the Members' views, to issue a questionnaire to them on the subject? If they would then meet representative Members round a table they could easily reach a solution satisfactory to all which would greatly strengthen the College and its diplomates.—I am, etc.,

REDMOND ROCHE,  
President of the Society of Members  
of the Royal College of Surgeons  
of England.

November 17th.

### UNIVERSITY OF GLASGOW.

The Samson Gemmell Chair of Pediatrics.

THE draft ordinance instituting the Samson Gemmell chair of Pediatrics was formally approved at the last meeting of the University Court. The chair, for which the late Mr. William Gemmell, brother of Professor Samson Gemmell, bequeathed the sum of £20,000, is to be a university chair connected with the Royal Sick Children's Hospital.

### ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

At a quarterly meeting of the Royal College of Physicians, held on November 6th, the President, Sir Robert Philip, in the chair, John Lindsay Boyd, M.D., was elected a Fellow of the College, and William Macrae Taylor, M.B., Robert Alexander Chambers, M.B., Atholl Robertson, M.D., and Joseph Primrose Leckie, M.B., were elected members. The Hill Pattison Struthers Bursary in Clinical Medicine was awarded to Mr. E. R. C. Walker, and the Hill Pattison Struthers Bursary in Anatomy and Physiology to Mr. T. D. Gould, and the Wood Bursary to Mr. I. A. G. L. Dick. A portrait of the late Sir Alexander Morison, and a baculum for the use of the Morison lecturer, was presented to the College by Dr. Alexander Blackhall-Morison.

### THE LATE DR. A. G. SIMMINS.

LAST April an appeal was made by an influential medical committee on behalf of the children of the late Dr. Alfred George Simmins and his wife, who died within a few hours of each other from influenza. There were three children and only for the eldest, a boy aged 6, had any provision been made. The following is the third list of subscriptions:

£21.—Anon., per Professor T. B. Johnston, Guy's Hospital Medical School.  
£15.—Some members of Lloyds.  
£12 10s.—Members of the British Medical Association and other practitioners of Warrington, per J. B. Naden.  
£10 10s.—Mildred Carhill, A. F. Hurst, North London Medico-Chirurgical Society.  
Anon., (per Professor Johnston), (Tasmania).  
£5 6s.—Mary Beadon, Sir G. F. Blacker, Gilbert Chubb, Stanley Dodd, Robert Hutchison, F. Langmead, Walter Spencer, H. L. Tidy, H. C. V., R. S. Willan (an old shipmate).  
£5.—Adolphe Abrahams, Captain Hamilton, R.N.  
£1.—G. B. Henriques.  
£3 5s.—S. E. Dore, H. Tudor Edwards, N. S. Finzi, Dr. Gilman (Singapore), E. G. Goldie, Professor T. B. Johnston, Dr. Livermore, A. J. M., G. T. Mullally, J. A. Ryle, F. D. Sauer, A. W. Stott.  
£3.—Charles Bolton, E. P. Poulton.  
£2 2s.—Eric Bailey, C. H. Bubb and W. A. Bulleid, R. Fenn, A. Green, J. Braxton Hicks, Montagu F. Hopson, H. Pinto Leite, Dr. Logan, F. Manser, H. Oddy, F. C. Odling, T. H. Oliver, R. P. Rowlands, Dr. Ruzsak, D. H. de Souza, Theodore Thompson.  
£2.—Anon. (per J. Curtis), J. C. Baker.  
£1 11s. 6d.—Drs. Rogers and Bell.  
£1 10s.—A. E. Druitt.  
£1 1s.—Anon., T. C. Blackwell, R. L. Crabb, Hubert Daw, J. S. Dudding, D. G. Greenfield, G. B. Good, G. W. Heckels, J. G. Jones, G. M. Kendall, H. A. Kisch, Dr. Lightwood, P. E. W. MacAdam, A. D. Marston, A. T. Scott, H. Steinbach, D. Tilbury, S. W.  
£1.—Francis Chown, A. B. de Freitas, Mrs. Sandiford.  
Sums under £1 amount to £2.

The total amount received is £1,260; the manner in which it will be administered will shortly be announced. Meanwhile, the Committee will be glad to receive additional subscriptions, which should be sent to the Treasurer, Simmins Appeal Fund, Royal Northern Hospital, Holloway, N.7.

### Medical News.

THE next session of the General Medical Council will commence on Tuesday, November 27th, when the President, Sir Donald MacAlister, K.C.B., M.D., will take the chair at 2 p.m., and give an address.

SIR ALFRED RICE-OXLEY, C.B.E., M.D., was presented on November 15th with his portrait in recognition of services rendered by him to the royal borough of Kensington during his three years' mayoralty. The presentation was made by Lord Phillimore at Kensington Town Hall, in the presence of a large company. The portrait has been painted by Mr. W. W. Russell, A.R.A. On the same occasion a diamond pendant was presented to Lady Rice-Oxley.

DR. L. G. HEILBRON of Amsterdam will read a paper on modern radiological technique at a meeting of the Röntgen Society, to be held at 8.15 p.m. on Tuesday, December 4th, at the British Institute of Radiology, 32, Welbeck Street, W.1. In order to commemorate the work of the late Professor Röntgen, the society has decided to make an annual award of £10 (or the equivalent in books or apparatus, at the option of the recipient) to the member whose contributions during the session relating to the science or practice of medical or general radiology are, in the opinion of the council, of sufficient distinction. The award will be made for papers or demonstrations read or shown for the first time and before the society relating to radiology in any of its aspects—theory, experimental work, technique, or the design of apparatus and equipment.

THE annual livery dinner of the Society of Apothecaries of London will be held in the Hall of the Society, Blackfriars, on Tuesday, December 4th, at 6.30 o'clock.

AN address on the ethics and psychology of neo-Malthusian birth control will be given by the Rev. Fr. Vincent McNabb, O.P., to a meeting of the Guild of St. Luke St. Cosmas and St. Damian, to be held at 3.30 p.m. on Sunday, November 25th, at the Hospital of St. John and St. Elizabeth, which is near Marlborough Road Station on the Metropolitan Railway.

A MEETING of the Naval, Military, and Air Force Hygiene Group of the Society of Medical Officers of Health will be held at 1, Upper Montague Street, Russell Square, W.C.1, on Friday, November 30th, at 5 p.m., when Major-General W. W. O. Beveridge, C.B., C.B.E., D.S.O., will deliver his presidential address. Medical men who have served with His Majesty's Forces are invited to attend.

LORD DAWSON will take the chair at a meeting of the Royal Society of Arts on Wednesday next, November 28th, at 8 p.m., when Sir H. J. Gairdner, M.D., will lecture on the effect of sun, sea, and open air in the treatment of disease.

A FESTIVAL dinner in aid of the London Jewish Hospital, Stepney Green, will be held on Monday, November 26th, at the Connaught Rooms, with Sir Humphry Rolleston, K.C.B., President of the Royal College of Physicians of London, in the chair.

PRINCESS LOUISE, DUCHESS OF ARGYLL, has become president of the National Health Society, in succession to the late Princess Christian.

MR. DUDLEY COX TROTT, F.R.C.S., surgeon to King Edward VII Memorial Hospital, Bermuda, has been appointed an unoffical Member of the Executive Council of the Bermudas or Somers Islands.

THE Sanitary Inspectors Examination Board have appointed Dr. A. T. Nankivell (M.O.H. Hornsey) and Dr. James Fenton (M.O.H. Kensington) to act as examiners during the year 1924.

THE annual autumn dinner of the Irish Medical Schools' and Graduates' Association will take place at Pagan's Restaurant on Tuesday, November 27th, at 7.30 p.m., Sir William Taylor, K.B.E., C.B., president, in the chair. Tickets (for ladies or gentlemen) 9s. each, from Dr. Holmes Mayrick, 48, Ennismore Gardens, S.W.7.

DR. HERBERT WILLIAM CROSSE, of the Middle Temple, was called to the Bar on November 19th.

AN intensive course will be held at the Hampstead General and North-West London Hospital, Haverstock Hill, N.W.3, from December 3rd to 15th. The course will occupy the whole of each day and will consist of clinics in the wards and out-patient department, etc., by members of the staff. Two special demonstrations will be given at the North-Western Fever Hospital (Lawn Road, Hampstead, N.W.3) on the diagnosis and treatment of infectious fevers, and during the second week four clinical demonstrations on neurological subjects at the Hospital for Epilepsy and Paralysis, Maida Vale. Tuesday, December 11th, will be devoted to clinical demonstrations in the departments of the Paddington Green Children's Hospital, W.2. The fee for the course is 4 guineas. Copies of the syllabus, with full particulars, can be obtained from the Secretary to the Fellowship of Medicine, 1, Wimpole Street, W.1.

THE following have recently been elected Fellows of the Royal Sanitary Institute: Colonel J. Allan Anderson, R.A.M.C., M.B., professor of hygiene in the Royal Army Medical College; Dr. E. L. Collis, Talbot professor of preventive medicine in the University of Wales; and Sir Leslie Mackenzie, M.D., medical member of the Scottish Board of Health.

DR. CHARLES SINGER is giving three lectures on the history of medicine, illustrated by lantern slides, at University College, London. The first dealt with anatomy and art; the second, to be given on Wednesday, November 28th, at 5 p.m., will deal with early medical books; and the third, on December 5th, with representation of disease in art.

THE new casualty department of the Royal Northern Hospital, which is the borough of Islington war memorial, will be opened by H.R.H. the Prince of Wales (president of the hospital) on Tuesday, November 27th, at 3 p.m.

DR. JOHN GRIFFITHS of Llandrindod Wells has been nominated a sheriff for the county of Radnorshire.

THE fiftieth anniversary of the New York Laryngological Society was celebrated on November 15th at the New York Academy of Medicine. An exhibition was held representing the most important contributions made to laryngology by New York surgeons.

A MONUMENT to Pasteur has recently been inaugurated at Montevideo by the President of the Republic.

DURING the first six months of 1923 only 9 cases of small-pox were notified in Germany, as compared with 1,627 in Switzerland and 1,219 in England and Wales.

THE *Journal of the American Medical Association* states that a former medical practitioner, whose certificate of registration was revoked two and a half years ago, was recently fined 200 dollars at Boston for continuing to have his name listed in the telephone book as a physician.

MR. GEORGE BLUMENTHAL of New York has presented the University of Paris with a gift of 250,000 francs to be used in the interests of science and art.

DR. CHARLES H. MAYO was elected president of the American College of Surgeons at its recent annual meeting held in Chicago.

THE sixty-fifth Congress of the Swiss Society for Psychiatry was held at Berne on November 17th and 18th, when the subject for discussion was psycho-analysis and psychiatry, introduced by Dr. Christoffel of Basle.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed, to the Editor at the Office of the JOURNAL.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the *British Medical Journal* are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

THE postal address of the *British Medical Association* and *British Medical Journal* is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the *British Medical Journal*, *Aitiology Westrand*, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY and BUSINESS MANAGER (Advertisements, etc.), *Articulate Westrand*, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera Westrand*, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bonillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### TREATMENT OF TABES.

"I." asks for advice in the treatment of a man, aged 44, who had syphilis twenty-two years ago, and had had lightning pains for eighteen years. The sphincter ani has been failing gradually for ten years, and the anus is now semi-patulous. There is no other sign or symptom of tabes. The Wassermann reaction, taken three or four times during the last ten years, has been negative, and so has the cerebro spinal fluid.

#### INTESTINAL ANTISEPTICS.

DR. LEONARD J. KIDD (London) writes in reply to Dr. Graham Grant (November 10th, p. 96): *Lumière (Comptes Rendus de l'Académie des Sciences, 1923, cxxvi, p. 540)* has found that the argemthioglycerine-sulphonate of sodium 1 gram by mouth in pilules put inside biscuits, has the power of almost completely sterilizing the faeces of dogs after four days' treatment; benzocaine failed. At the time of publication clinical experience confirmed these experiments. This silver salt is prepared by heating to a high degree; it contains 35 per cent. of metallic silver, is free from the usual bad effects of silver salt, and is only very feebly toxic by mouth. I have found iron perchloride to be excellent as a deodorizer of the faecal evacuations.

DR. J. PRIE (Leamington Spa) writes to suggest the use of kaolin, which, he says, acts because of its high absorbent power for alkaloidal poisons and "its high insulating capacity for inflamed cells." The preparation is made as follows: Add 5 oz. of kaolin to 9 oz. of water; mix gradually, with constant stirring, until a fine cream is formed; then add 1 oz. of mucilage of tragacanth, the stirring being continued. The dose is a wine-glassful every four hours for three days, nujol being given during the remainder of the week; the kaolin is repeated at the beginning of the next week and followed again by nujol. The diet must be attended to at the same time.

DR. L. WHEELER (London, W.) suggests that for the condition in question dimol should be given in sugar-coated tablets, as in obstinate cases there is often a marked deficiency in pancreatic enzymes, so that a keratin coating is not dissolved. He recommends three after each meal. Dr. Wheeler has treated many cases in the East successfully by this method, sometimes assisted by rectal lavage with silver nitrate solution (5 grains in 10 oz.), if tenesmus or blood indicated active congestion or ulceration of the terminal end of the colon. Small doses of castor oil might be a useful adjuvant. Our correspondent assumes that Dr. Graham Grant has eliminated the possibility of carcinoma.

\*. The search for an efficient intestinal antiseptic has, on the whole, yielded disappointing results. A review of the older work on the subject is given by N. M. Harris (*Journ. Amer. Med. Assoc.*, 1912, 56, 1544). This article shows that most of the reputed intestinal antiseptics have little or no action. Positive results have, however, been obtained by various workers who used preparations of the heavy coal tar oils. The proprietary remedies, dimol (mentioned by Dr. Graham Grant) and kerol (which is mentioned by another correspondent) belong to this class. Sir L. Rogers (*Ind. Journ. of Med. Res.*, vol. i, No. 2, 1914) found that cyllin and izal were of some value in bacillary dysentery. The fact probably is that symptoms such as described by our original correspondent may be due to one of several conditions. The healthy intestinal canal has its own

Local sepsis and drug addiction are closely related, and though the former may by its physical effects lead to drug addiction, yet in a similar manner the drug habit, by its lowering effect on the immunity mechanisms in the body, may predispose to the development of focal infections, especially those of dental origin.

#### One Drug Habit Leads to Another.

This is an axiom which may be laid down for almost all cases. The taking of a particular narcotic drug leads to an unstable condition of the nervous system which is indicated by effects on the higher mental faculties. In other words, the soil is prepared for narcotic stimulation of any kind. Thus the morphine addict frequently resorts to cocaine or alcohol as alternative measures of relief for his craving for drugs of any kind available becomes almost an obsession. In cases of drug addiction of long standing it is frequently found that a combination of drugs is used, morphine or heroin with cocaine or alcohol being the commonest combination.

#### Drug Addiction of Long Duration.

There can be little doubt that when a narcotic drug has been taken for a period of years organic changes result in the nervous system, and probably other changes of a biochemical nature occur which alter the metabolic processes of the body. In such cases cure is very difficult and sometimes almost impossible. The drug has become a necessary adjunct to the working of a disorganized nervous system; in other words, it has become an abnormal food.

Every physician who has studied drug addiction is acquainted with such cases where attempts to cure have repeatedly failed and where the daily allowance of a minimum amount of the drug is a necessity. In such cases the withdrawal of the drug may lead to the complete physical and mental breakdown of the individual. He cannot, without its artificial aid, perform the duties of life, and the withdrawal may lead to uncontrollable crimes of violence. Numerous examples of this kind have occurred amongst addicts engaged in artistic or literary work often of high grade.

In Eastern countries amongst the lower castes of society the taking of opium by the month causes marked addiction diseases. In India certain individuals become so accustomed to a daily ration of opium that they cannot carry on their daily work without it. During the war in Mesopotamia several cases of opium addiction amongst Indians of low caste attached to the Labour Corps were brought to my notice. Often a very small amount—one or two grains a day—was sufficient to maintain an equilibrium and enable them to perform their duties. In a few cases complete mental breakdown and times of violence of an irresistible nature occurred when from some reason the addict was unable to obtain his daily dose of opium. In the Pen colonies of England and landanum and opium used to be not uncommon; possibly the effects arose from the taking of the drug to counteract the effects of malaria which was prevalent in former days, and for which it was a common remedy. The landanum and opium habit became firmly established, and the unfortunate individuals affected became addicts who existed on a low grade of physical and mental health, for the maintenance of which the drug was obtained at all costs. The taking of landanum and opium by the poorer classes in this country has fortunately become very rare.

#### Fetious Causes.

Opium and its preparations—morphine, heroin, and cocaine—are sometimes first taken by individuals who have been told that the drugs have a stimulating effect and produce brilliance in thought. In some persons small doses of these drugs at first have the effect of cutting off inhibitory impulses, and so for a transient period of minutes self-consciousness or stage fright may be forgotten, and a false sense of well-being produced.

An analogous use of the drugs is in the dopping of horses, a practice which is severely condemned and punished by the law.

This is one of the commonest causes. The addict desires nothing so much as the leading astray of those innocent of this terrible vice. The pleasures following the dope are painted in most glowing colours and the neophyte is besought to partake of them. The first few doses may actually produce transient pleasurable sensations, but each is followed by a sense of intense depression and misery, which calls loudly for removal by a further dose. In this manner drug addiction of the vicious type spreads rapidly amongst those associating with its votaries.

Morphine, heroin, and cocaine are deliberately taken by persons of vicious associations in the hope that the stringers of new sensations may be played upon. In some cases, especially amongst women of the underworld, cocaine and heroin are taken commonly as snuff, with the idea that transitory mental brilliance and attractiveness are produced. Prostitution and sexual vice are closely associated with drug addiction. Thus cocaine may in the early stages of addiction have an erotic effect, and there is evidence that it is an important factor in the causation of unnatural sexual vice.

Morphine and its derivatives appear to have a sedative effect on sexual impulses and to lead to impotence and sterility. These drugs are taken often by those sexually vicious to stifle the calls of conscience. So great are the cravings of drug addiction that cases are known to me where honours in order that a supply of the drug may be obtained.

#### Drug Addiction a Disease.

The taking of a narcotic drug of addiction for a few doses may be termed a vice, but if the administration is continued for a month or so a true disease condition becomes established, with a definite pathology and symptoms. The drug addict, provided that he has a certain allowance of his drug, is an individual on a low plane of physical health. The complexion is sallow, he is emaciated, and there is evidence of a general lack of function of the secretory organs. The mental symptoms are shown by weakness of character and will, and lack of moral sense. In some cases a drug addict may show even to an experienced observer few, if any, abnormal signs. The opium or morphine addict, if having his necessary allowance of the drug, may conduct himself normally from the amount of his work, for extensive periods, carry on his work in life. The cocaine addict undergoes a more rapid deterioration, both mentally and morally, and is apt to perform criminal acts.

The "withdrawal symptoms" of addiction disease are most characteristic. The sudden stoppage of the drug leads quickly to characteristic symptoms which are both physical, and subjective or mental. These have been well described by Dr. Harry Campbell in his recent able paper on morphine addiction read before this Society (April, 1932).

The objective symptoms—freeness of the heart's action, tremors, vomiting, purging, and sometimes actual collapse—are unmistakable. In addition there are subjective symptoms, such as pains in the limbs and body of a distressing character. The mental symptoms experienced by the patient are those of restlessness and extreme mental suffering.

The withdrawal symptoms are at once relieved by a dose of the drug. In a continued addiction, the prevention of withdrawal symptoms is in the dopping of horses.

natural method of limiting the intestinal flora, and not very much can be hoped from antiseptic drugs. Harris, in the article quoted, concluded: "Regulation of the diet, together with the evacuation of the bowels, is the most effectual method that we have at hand for reducing an excessively high bacterial content of the large intestine."

## INCOME TAX.

## A Branch.

"E. G." started a branch surgery on April 1st, 1923. How does he calculate the liability to tax?

\*.\* A branch started (not taken over) is to be regarded as an extension of the existing practice of such a nature as to leave undisturbed the three years' average basis of liability. "E. G." is therefore liable to return for assessment as for the financial year his average profits of the three years to April 1st, 1923, which of course do not include the branch profits or losses. For 1923-24 those profits will commence to affect the three years' average, but will not do so to the full extent until 1926-27.

## Book Debts.

"J. S. H." started a practice on April 1st, 1923, and the inspector of taxes claims in these circumstances to base the assessment on "bookings" but refuses to make any allowance for doubtful debts.

\*.\* The inspector is following the usual course in basing the assessment of a new practice on bookings, but his refusal of an allowance for doubtful debts is unjustified in law and unreasonable in its results. "J. S. H." should prepare a list of his book debts as at April 1st, 1924, and put a valuation on each; the difference between the nominal total and the total of the valuations should be claimed as an allowance for bad and doubtful debts. We are of opinion that such a claim, if kept within the limit of obvious reasonableness, would be admitted on appeal by a board of commissioners.

## Car Replacement.

"T. B. E." bought a motor cycle in 1920 for £68 and a motor car in 1921 for £350. He has recently sold the former for £15 and the latter for £100 and bought a second-hand car for £200.

\*.\* The most "T. B. E." can claim is the actual out-of-pocket cost of replacing the car—that is, £200 - £100 = £100. If and when he buys another cycle (or another car for simultaneous use with the one he has) he can claim the loss on the old cycle—that is, £53 against that expense; but there is no relief for the loss on sale as such. The allowable expense is, of course, to be set against the gross profits of the year 1923, and *prima facie* would not affect the income tax assessment for that year.

## LETTERS, NOTES, ETC.

## CHRONIC INTESTINAL STASIS AND CANCER.

DR. LIONEL SELLS, Uganda Medical Staff, retired (Longfield), writes: With reference to Sir W. Arbuthnot Lane's remarks on cancer in native African races in your issue of October 27th (p. 745) I beg to state that I saw a case of carcinoma of the breast in an Acholi woman close to the Naqai Hills, north-west of "Lake" Kirkpatrick, in January, 1915. The district is closed to Europeans and Indians; of the only Europeans ever there long years ago one was murdered, and the other came, avenged him, and went. Duke in his report for 1921 briefly says he examined an epithelioma of the eyelid from a native, but gives no particulars of race, etc. I have travelled much in the bush and have inoculated thousands for plague and closely examined seventeen thousand of all tribes for army porters during the war, and this is the only case I ever saw.

"SENEX" writes: I am surprised that Sir Arbuthnot Lane's recent recapitulation of his well known views on the upright posture-constipation-cancer sequence, has not hitherto elicited any information from those interested in the study of comparative pathology. For I am informed that in animals cancer is quite a common disease; indeed, it is said that cancer of the breast is met with in dogs, for instance, almost as frequently as it is in human beings. It is true that my acquaintance with dogs is quite fortuitous, but as far as my observation goes—and there are a good many in this street—they are very rarely constipated; certainly those that frequent my doorstep never are. Here we have tangible evidence of a fundamental difference which would appear to be sufficiently important to engage Sir Arbuthnot's attention. Is it possible that there is a flaw in his reasoning—is it conceivable that we have all been on the wrong tack, and that, after all, it is not that constipation is the cause of cancer, but that cancer induces constipation?

## MEAT AND CANCER.

MR. J. K. PEDLEY, L.D.S.R.C.S.Ed. (Tunbridge Wells), sends us a letter on the subject of the possible relation of the greater consumption of meat to the increase of cancer. If meat is given to a carnivorous animal it is (he writes) not kept in the mouth, but is immediately swallowed. In the light of comparative anatomy man was meant to be a non-flesh-eating animal. The almost entire absence of dental caries amongst the natives

Sir Arbuthnot Lane writes of (in India, Africa, and South America) also has surely something to do with their freedom from this scourge. As soon, however, as the native child commences to eat meat the temporary teeth go to pieces—the fibres of the meat getting jammed between the teeth make way for the enamel-destroying carbohydrate of the white flour, which is given the child in imitation of the European. Amongst pre-war Germans, on becoming more wealthy, meat at every meal was the order of the day; as a consequence, I think statistics would show a greater prevalence of cancer in Germany than any country in Europe. In conclusion, until the legislature gets to work to make the sale of an emasculated flour a penal offence, and until the public realize that meat should not form the basis of their diet, cancer will still take its toll of human life.

## THE DANGER OF AMYL NITRITE IN COLLAPSE.

DR. ETHELBERG HEARN (Sherwell, Isle of Wight) writes: I was interested in the case described by your correspondent under the above heading in the JOURNAL of November 10th (p. 906), first, because it must be a rare occurrence for a patient to pass "into a state of dangerous collapse" under nitrous oxide administered with oxygen; secondly, that amyl nitrite is the one drug above all others that will help us when such symptoms arise under the influence of nitrous oxide alone, and which, in my opinion, should be at the elbow of every anaesthetist when administering it. Many years ago, before the introduction of the nitrous oxide-oxygen method, I administered nitrous oxide to a lad about 18 years of age for the extraction of two teeth. He suffered from congenital heart disease, and twice previously I had given him gas for single extractions with quite satisfactory results. On this occasion, however, after the teeth were removed, I was alarmed to find that he made no signs of recovery—indeed, cyanosis deepened, breathing had apparently stopped, and he appeared lifeless, but the sudden application of amyl nitrite acted like magic; he gave a deep gasp, started breathing rapidly; his colour, never very good, improved, and he soon recovered consciousness. Time being the essential factor in such cases, to examine the pulse and auscultate the chest seems to me like courting trouble; visual signs should be quite sufficient to prompt the anaesthetist to act, and that instantly.

## A CLEANLY AND SILENT MILK CHURN.

In its passage from the cow to the consumer milk has to run the gauntlet of contaminations of various kinds. Not the least in importance are those which are associated with its journey in bulk from the dairy farm to the retail distributor in the large upright cans—or, as they are styled in the trade, churns—which are familiar objects to most railway travellers. Most of these receptacles in general use are far from satisfactory—the lids are not tightly fitting and are so constructed that the upper portion of the churn collects dust and dirt over which the milk has to pass when the churn is emptied; there are also ventilating apertures through which dust or rain can gain an entrance, and too often the abstraction of milk during transit and its replacement by water is not at all a difficult matter. A further drawback to the use of the churn in common use is the noise and clatter which accompanies its removal from platform to railway van and vice versa—an intolerable nuisance to those who have to travel by night time. Mr. A. S. F. Robinson, A.N.I.C.E., of Barham, Beccles, has endeavoured to remedy these defects by producing a sealed churn provided with a large rubber ring at its foot and neck, and covering the handles with rubber. He claims that by its use there is no wastage or contamination of milk during transit, and that it can be moved noiselessly. If his claim can be substantiated he will have done a real service to his fellowmen.

## RECOVERY AFTER EXTENSIVE FRACTURE OF THE SKULL.

F. D. (Nice) writes: I noticed a reference, in a newspaper recently, to the case described in the BRITISH MEDICAL JOURNAL of October 13th (p. 647) of an Egyptian who lived and worked for eleven years with a fractured skull, and I think the following instance is interesting of a somewhat similar case of an Egyptian, which occurred some years ago, and in which I knew all the persons concerned:

An Arab was painting the iron lattice framework of the Ashrafi lighthouse in the Red Sea, at the entrance of the Gulf of Suez. He fell a distance of forty feet from the framework on to the cement caisson of the base of the lighthouse, striking a small dinghy swung out from davits from the framework, falling flat on his back—insensible, and apparently dead—with the base of the skull broken. The chief light-keeper and his two mates examined the skull and found a piece of the bone out, and brains with it, on the caisson. The chief light-keeper pattered up the brains with a spoon, put them back into the skull, and fitted the piece of bone into its place, making a sort of cement of coffee grounds. A box was made of old packing cases, into which the man was put, and a ship signalled asking for a doctor, who came, and the box with the man in it was put on board the ship and taken to Suez to the hospital. It was found he had several ribs broken, besides the injury to the skull, in spite of which, in three months' time, he was down again at the lighthouse at work.

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 29, 30, 31, 34, 35, and 36 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32 and 33.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 251.

Withdral symptoms of addiction disease are not accepted as forming a definite symptom-complex of characteristic type. They are not symptoms which are purposely assumed by the patient with the object of obtaining a further dose of the drug. The objective symptoms described are a sufficient proof of this.

The experimental production of morphine addiction disease in dogs, and the manifestation of a similar symptom-complex of withdrawal symptoms, have furnished additional evidence that drug addiction is a true diseased condition. A most interesting case or symptoms of morphine withdrawal in a newly born infant has been published by Dr. T. A. Van Kleeck in America.

The mother had been a morphine addict for years, taking from 6 grains daily during her pregnancy. The child at birth appeared normal, but on the second day cardiac failure, sweating, cyanosis, vomiting, and diarrhoea rapidly developed and the condition became alarming. In view of the treatment for shock were tried without success. The usual methods of resuscitation were tried without success. In view of the form of 3 minims of compound tincture of camphor, was given and repeated every one and a half hours for three doses. The symptoms of collapse cleared up as if by magic. On the third and fourth days the same symptoms of collapse occurred, and were relieved at once by the same methods of treatment. After the fourth day the mother was able to suckle the child, which then remained in good health.

In this case it was clear that the child suffered from withdrawal symptoms of addiction disease on the second, third, and fourth days of life. It also appeared evident that the addiction disease was transmitted from mother to child. Different morphine to prevent withdrawal symptoms was present in the milk of the mother, who continued to have a usual daily allowance of morphine. The above case is strong evidence that drug addiction is a real pathological condition or disease.

### PATHOLOGY OF DRUG ADDICTION DISEASE.

That the condition is caused by morphine and its allies is well known, and the symptomatology is well recognized as definite symptom-complex. The explanation of why withdrawal symptoms occur is yet to be worked out. American writers, foremost amongst whom is Dr. E. S. Bishop, assert that the taking of morphine leads to the formation of an antidotal substance in the body, which neutralizes the antidotal substance is itself very toxic, and that it continues to be produced in the body if the drug is discontinued. At this stage withdrawal symptoms develop and are only relieved by a further dose of the drug, which by neutralizing the toxic antidotal substance. This theory, fascinating as it seems in the ready explanation of the production of withdrawal symptoms, has not yet received adequate experimental confirmation. Professor E. Dixon, in an address on the drug habit (British Medical Journal, November 19th, 1921), states that neither other nor any other drug causes antibody formation. On the other hand, Valenti rendered dogs tolerant to morphine found that on suddenly stopping the drug typical withdrawal symptoms occurred. He alleged that injection of the serum from dogs showing withdrawal symptoms caused at symptoms to develop in normal dogs. Professor Dixon suggests as an explanation of withdrawal symptoms that nerve cells, after prolonged narcosis, become awakening hyperexcitable, and that a further dose of is necessary to allay this condition. The fact that passing quantities of morphine and cocaine are required for addicts can be accounted for by the increased power of destroying these drugs which is developed by the tissues of the body. Other explanation of addiction disease which, I think, is the subject of pathologic research.

Other explanation of addiction disease which, I think, is the subject of pathologic research.

Scientific research is sorely needed on the pathology of drug addiction, and there are hopeful signs of light thrown on the subject in the near future, since investigations are already in progress. The Ministry of Health has recently appointed a committee to inquire into the substances for cocaine and possibility of drug addiction arising therefrom. It is that valuable information may be forthcoming from inquiry which will throw some light on the pathology of addiction.

### TREATMENT OF DRUG ADDICTION.

Each individual case of addiction requires careful consideration as to the line of treatment to be adopted. not propose to discuss in detail the method of treatment since these were fully dealt with by Dr. Harry Campbell in his recent paper. General lines of treatment only are considered. When the addiction habit is once established it is essential that treatment should be commenced without delay. Ambulatory treatment almost always fails and should be attempted. As Dr. Bishop has forcibly pointed out, there is no panacea for the cure of drug addiction, and the "cures" and "patent medicines" are worthless and do more harm than good. Some of the advertised as cures have been found actually to counteract the only treatment that gives a hopeful prospect of cure as hoped as is the case in other diseases. A great drawback in the treatment of drug addiction is the feeling of hopelessness experienced not only by patients but often, it is to be feared, by their doctors. Treatment in an institution or nursing home with complete supervision is essential. After the preliminary period of investigation and removal of associated predisposing factors, during which a minimal allowance of the drug may be necessary, withdrawal should be effected. Where the general health of the patient is good and withdrawal is of short duration sudden withdrawal is admissible. I think the dangers of sudden withdrawal have been somewhat exaggerated, and in many cases the institution that his cure is hopeless. It has been my experience that the general condition of the patient is good and that there is every facility for careful nursing, sudden or very gradual withdrawal may be safely effected and is the most satisfactory method.

In confirmation of this view I may quote the results of an experience of medical officers of prisons in this country which have been kindly given me by Sir Malcolm Delvingne. is a frequent occurrence for drug addicts to be sentenced to them has been sudden withdrawal of the drug. In case have any alarming symptoms occurred and in only very few isolated patients has any narcotic drug been given at all. In these cases on one or two occasions a very small dose of liquor morphine has been given by the mouth, the never has any narcotic drug been given hypodermically.

### Sudden Withdrawal.

Where the general health of the patient is good and withdrawal is of short duration sudden withdrawal is admissible. I think the dangers of sudden withdrawal have been somewhat exaggerated, and in many cases the institution that his cure is hopeless. It has been my experience that the general condition of the patient is good and that there is every facility for careful nursing, sudden or very gradual withdrawal may be safely effected and is the most satisfactory method.

## Medicine.

### 360. Experience with Insulin in Fifty Cases of Diabetes.

In this article C. v. NOORDEN and S. ISAAC (*Klinische Wochenschrift*, October 22nd, 1923, p. 1963) record their experience of insulin in fifty cases of diabetes. Many of these had long been under observation, and hence the authors were able to compare the results of insulin treatment with the results of other treatment in the same patients. Of the superiority of insulin treatment over all previous methods they admit there can be no doubt. Good results were obtained even in cases in which previously there had been the greatest difficulty in diminishing the sugar and acetone excretion to a tolerable amount. A preliminary dietetic treatment is necessary to enable us to judge of the metabolism and to bring the glycosuria to the minimum. Smaller doses of insulin are then required to check the glycosuria. As the action of insulin continues only for three or four hours it should be given three times a day before meals. As regards the diminution of the blood sugar by insulin the authors point out that in the intervals between the separate injections, and especially in the night, the blood sugar rises again, and that the estimation of the blood sugar during fasting gives no clear indication of the action of the insulin on the hyperglycaemia. Rapid diminution of the blood sugar curve should be avoided, otherwise cerebral symptoms and loss of consciousness may occur. The influence of insulin in diminishing the acetone bodies is astonishing, and the greatest triumph of the treatment is its surprising effects on diabetic coma. The authors have been able to check some cases of commencing diabetic coma by insulin. Improved tolerance is obtained after insulin treatment, but the extent thereof has yet to be decided. Banting's discovery is an epoch-making event, and an invaluable gain in the treatment of diabetes. The authors consider that insulin acts on the liver and renders glycogen formation again possible, and ensures a fixation of the glycogen formed. In many respects insulin is an antagonist of adrenaline.

### 361. The Parathyroids and Paralysis Agitans.

E. BERGMAN (*Upsala Läkarsällnings Förhandlingar*, September 7th, 1923, p. 405) has treated two cases of typical paralysis agitans and four cases of Parkinsonism following epidemic encephalitis with parathyroid grafts. The glands were taken from calves two to four hours after death and grafted into the subcutaneous tissues of the abdominal wall after a microscopic examination had shown that the excised glands were really parathyroids. Only in one case did definite improvement follow. The patient was a lad, aged 13, suffering from Parkinsonism, and as the improvement did not occur till two months after the grafting this could hardly be given the credit. The author also gave parathyroid substance daily by the mouth to four of his patients, and in two cases of Parkinsonism he gave parathyroid extract by parenteral injection. No great improvement followed, and the author admits that his investigations failed to support the teaching that paralysis agitans is a disease of the parathyroids.

### 362. The Danger of Indiscriminate Iodine Medication in Goitre.

O. ROTH (*Schweiz. med. Woch.*, September 13th, 1923, p. 865) deplors the present tendency of pharmacists, school teachers, and other persons in Switzerland to advise their friends to dose themselves with iodine. This tendency is the outcome of the official propaganda in favour of preventing goitres in the public schools of Switzerland by means of the occasional swallowing of some iodine tablets. It is most unwise to describe as harmless any dose of iodine, however small it may seem, and the author refers to thirty cases, observed by himself, in which iodine had been taken by patients without medical advice. In most of these cases only slight iodine poisoning was observed, but it was troublesome enough. There were, however, cases in which severe and permanent injury was inflicted, and some of these cases showed that a dose of iodine which may be well tolerated by a school child, provokes severe iodine poisoning in a susceptible adult. The susceptibility of a person to iodine seems to vary from time to time, and the author records the case of a domestic servant aged 25, who took eight iodine tablets (Jodostarin) within four weeks with impunity. A year and a half later she again took eight tablets within four weeks, and she soon afterwards developed signs of severe Graves's disease. The lesson of this

and other cases recorded by the author is that there is no minimum dose of iodine which can be prescribed in every case with impunity. This being so, the prophylactic treatment of goitre must be kept strictly in the hands of the medical profession. One of the worst cases recorded by the author was that of a woman, aged 35, who suffered from goitre, and who was induced by the recent iodine propaganda to take forty-two chocolate-coated iodine pastilles in the course of fifty weeks. Although signs of iodine poisoning appeared after about four months, she continued to take iodine, and she developed all the characteristic signs of iodine poisoning, as well as severe dilatation of the heart and arrhythmia perpetua which proved refractory to quinidine.

### 363.

#### Auto-pyotherapy.

E. MAKI (*Deut. med. Woch.*, August 31st, 1923, p. 1147) has treated more than a hundred cases of localized suppuration by aspirating the pus and reinjecting 1 c.cm. of it under the patient's skin. The injections are repeated every fifth day as often as necessary. In the case of cold tuberculous abscesses, from 1 to 10 c.cm. of the pus are re injected. The therapeutic effect would seem to depend on the patient being given his own pus; the injection of cold pus from another patient into a person also suffering from a tuberculous abscess is not beneficial, at any rate to the same extent. Most of the author's cases represented acute localized infections with streptococci, staphylococci, and various other pathogenic germs. In no case did this treatment give rise to a progressive infection with phlegmon and dissemination of the disease, and in about 30 per cent. there was not even a local reaction. In another 30 per cent. there was a slightly painful infiltration, which disappeared spontaneously in eight to ten days. There were, however, some cases in which a strictly limited abscess formed at the site of injection, disappearing after aspiration or spontaneously. As a rule, there was no febrile reaction, and the temperature never rose more than 1° C. Indeed, in several cases the temperature fell directly after an injection, coming down step by step after each injection. In half an hour to an hour an injection would be followed by a leucocytosis, the total number of leucocytes being often doubled in ten to twelve hours. The cases treated included suppuration of lymphatic glands, empyema, mastitis, perioritis, mastoiditis, osteomyelitic abscess, and (one case) gangrene of the lung. In this last case there was a cavity in the lower lobe of a child's lung, exploratory puncture of which yielded stinking pus, containing a mixed bacterial flora. Rapid improvement followed the injections, five of which were given at five-day intervals.

### 364.

#### Lichen Planus of the Glans Penis.

D. W. MONTGOMERY and G. D. CULVER (*Amer. Journ. Derm. and Syph.*, July, 1923, p. 73) state that lichen planus in many of its features is so like an infectious disease, and especially so like syphilis, that there is a great danger of mistaking it for that disease, particularly if the lesion is on the genitals. Of 114 cases of lichen planus in males under their observation 21, or 18 per cent., showed the eruption on the glans penis. In some instances lichen planus may be limited to the genitals, and in such cases both the physician and patient may believe the disease to be venereal, the more so when small papules on the glans are associated with hypertrophic papules on the scrotum resembling condylomata. In some instances lichen planus of the glans may be indistinguishable from an ordinary balanitis, but in two cases of the kind seen by the authors the diagnosis of lichen was established by characteristic lesions elsewhere. In other cases the condition may resemble leucoplakia, owing to the thickened white appearance of the epithelium and the absence of papules, and a diagnosis can only be made by the coexistence of undoubted lichen in other situations and the disappearance of the penile lesions under treatment at the same time as the lesions in other situations. Lastly, lichen planus of the glans may resemble the scar left by a chancre, as in the case of a physician who had a quadrilateral lesion on the lower lip with a characteristic lacework surface and other unmistakable lichen lesions on the buccal mucosa. The number of papules on the glans varies in different cases. Sometimes, as in two of the authors' cases, there may be only one lesion, or they may be innumerable, or the papules may be arranged in one or two groups, an annular arrangement being characteristic. Another frequent manifestation of lichen is the formation of pigmentation,

**Gradual Withdrawal.** In cases of addiction of long duration, especially if the general physical condition is of low standard, gradual reduction is advisable. In cases of this type hypsone has been advocated, a mild hypsone habit being produced for thirty-six to forty-eight hours by repeated small doses given hypodermically. At the end of this no morphine is given. The advantage of the hypsone treatment is that in a long-standing case sudden withdrawal is effected. The disadvantage is that there is apt to be a more pronounced development of symptoms during the period of after-treatment. It is doubtful whether any ultimate advantage is gained from hypsone treatment.

#### After-treatment.

After withdrawal has been effected the after-treatment is very important, and in this stage, in addition to general hygienic and medicinal methods, psychotherapeutic treatment is most valuable. The cultivation of the will power and of a feeling of hopefulness and certainty of recovery are most important factors for success in this phase of the treatment.

#### Cases of Long Standing.

In cases of drug addiction where large doses have been taken for many years, and where the nervous and physical condition of the patient is of a low standard, the prospect of cure is poor, and in some cases practically hopeless. The minimal daily allowance of the drug spaced at as long intervals as possible should be accurately determined, and adequate steps taken that the allowance is not exceeded. In this type of case it is probable that permanent organic changes of a degenerative nature have occurred in the nervous system. During the treatment of drug addiction it is important that alcohol should be avoided, as otherwise alcoholism is likely to follow on the cure. Similarly allowance is best cut off, or reduced to the smallest.

#### Mexico-Legal Aspects of Drug Addiction.

The world-wide appreciation of the dangers and evils of drug addiction was exemplified by the International Opium Convention which met at the Hague in December, 1911, and January, 1912. A general course of action was agreed upon to which the twelve countries co-operating gave sanction, but it was not to become effective until the other countries not participating had agreed. The final attainment of a satisfactory result was delayed by the outbreak of the European war. The Peace Treaty of Versailles contained amongst its clauses some tending to the ratification of the Opium Convention. Under the terms of the Opium Convention the consenting nations agreed to frame acts dealing with the dangerous drugs opium, morphine, and heroin. In this country the Dangerous Drugs Act was passed in 1920, and under Section 7 of this act power was given to make regulations for controlling the manufacture, sale, possession, and distribution of the drugs in question. In May, 1921, regulations were issued dealing with the carrying out of the provisions of the Dangerous Drugs Act, and in 1922 and 1923 certain amendments were made to these regulations.

During the war and down to the passing of the Dangerous Drugs Regulations, control of the sale of narcotic drugs was obtained by the Army Council Order under the Defence of the Realm Act in May, 1916. Orders were made dealing with cocaine and opium which were similar in character to those of the Dangerous Drugs Regulations of 1921. The Defence of the Realm Act Order of May, 1916, dealt with the sale of narcotic drugs to any member of H. M. Forces, and permitted the sale of opium, morphine, cocaine, and heroin only on the prescription of a registered medical practitioner, dentist, or veterinary surgeon. The prescription had to be written out in accordance with the prescribed details, and was to be retained by the pharmacist or dispenser. The scope of this order was wider than that of the Dangerous Drugs Regulations of 1921, for it included in addition barbitone, chloral hydrate, codeine and heroin, Indian hemp, and snuff and its homologues. The

I know also that moderation and restraint have been shown, as far as possible, by the Home Office authorities and the Ministry of Health in the carrying into effect of the principles of the Regulations. In the difficult position created by the Dangerous Drug Regulations it must be borne in mind that the object for which they were framed can only be satisfactorily attained by the loyal co-operation of the professions concerned with the State authorities. It has been said that a coach and four can be driven through an Act of Parliament, and it would not be difficult for the letter of the law regarding dangerous drugs to be followed and its spirit evaded. For instance, dilution of dangerous drugs beyond the limits laid down in the Regulations would not prevent their possible use for addiction purposes.

Loyal co-operation will be best endeavored for by moderation and restraint by the authorities, when technical breaches of the Regulations occur, in which there is evidence that reasonable and proper care has been taken to avoid them. For example, a difficulty arises in the case of clearly forged prescriptions; the onus of the discovery of these appears to rest with the pharmacist, and, in some cases, treatment in cases of addiction, except in the very rare cases where the drug is taken as drink, and then possibly the provisions of the Inebriates Act of 1898 might be called into action. For practical purposes this Act is quite powerless in dealing with drug addiction. From the purely medical aspect it would, in my opinion, be desirable that legal powers should be given whereby drug addiction can be treated by compulsory institutional treatment. At a recent discussion at the Mexico-Legal Society (March, 1923) on this subject the legal opinion was emphatic against the advisability, at present, of institutional treatment being made compulsory in cases of drug addiction. Moreover, the special institutions and staffs that would be required for the treatment of large numbers of cases of drug addiction do not, at present, exist in this country, and provision for them would be necessary before any legal enforcement for compulsory treatment were enacted.

Dr. H. A. Burridge gave the Mexico-Legal Society last March a very carefully thought out paper on "State effort to rescue victims of drug addiction." In this paper the hardships caused to drug addicts and to the medical profession in the United States by the harshness of the existing laws and regulations were forcibly dealt with.

which may persist long after the disappearance of the papules. It was a remarkable fact that pruritus, which is a frequent and often distressingly severe symptom of lichen, did not affect the glans in any of the authors' cases.

### 365. Non-organic Heart Murmurs in Early Infancy.

CAPITE (*La Pédatrie*, October 1st, 1923, p. 1060), in a synthetic review of the above question, uses Vaquez's classification of murmurs—organic, functional or intracardial, and non-organic or extracardial. Potain taught that non-organic murmurs were due to the distension of a prolongation of the lung during cardiac systole, and hence they are usually systolic in time, but diastolic extracardial murmurs have been described, and they are not confined to the apex. Variability is a frequent sign in non-organic murmurs, especially in children—softness in character and absence of propagation are other signs. Pericardial friction is rougher and is not propagated, and has no relation to the cardiac cycle. Besides these cardio-pulmonary murmurs there are the group due to cardiac dilatation from emotion and in the course of acute illness—for example, typhoid fever. In anaemia functional murmurs may be due to diminished viscosity of the blood. Some authors deny the existence of functional murmurs in very young children, and it is difficult to say whether a murmur is functional or organic. The x-ray diagnosis is not very trustworthy, and practically one has to wait and see whether the murmur disappears in time or remains persistent before a certain opinion can be given.

## Surgery.

### 366. Retropharyngeal Abscess.

D. E. S. WISHART (*Canadian Med. Assoc. Journ.*, September, 1923, p. 635), in reporting a fatal case of retropharyngeal abscess with erosion of the internal carotid artery, discusses the pathology and treatment of this condition. In his opinion the cause of practically 100 per cent. of the cases of retropharyngeal abscess is suppurative lymphadenitis. During the past eight years forty-one cases of retropharyngeal abscess were seen by him in the Hospital for Sick Children, Toronto; in twenty-four of the cases the onset was not attributed to any definite cause, but in seventeen, or 40 per cent., there was an accompanying infectious disease in the nose or ears. The condition is essentially one of infancy and reliance for the history has to be placed upon parents, who are very often poor observers; the most frequent causes of parental anxiety were (1) that the child was breathing or swallowing with difficulty, and (2) the appearance of swelling on one side of the neck. Retropharyngeal abscess must always be considered an emergency calling for immediate evacuation of the abscess; the operation is safe if it is properly performed. No anaesthetic is necessary; the child is swathed, placed on its back on a table, and a mouth gag inserted. Under inspection by reflected light the tongue is depressed by a tongue depressor held by the surgeon in his left hand. He then takes in his right hand a pair of special pointed tonsil scissors, which are plunged through the apex of the pharyngeal swelling and opened wide so as to make a vertical slit. All this is the work of a few seconds, but the important part of the operation follows. It consists in the attendant at once rolling the child on its side, while the surgeon with the tongue depressor holds the tongue down and the mouth open so that the pus, unable to find its way into the trachea and larynx, flows freely out of the mouth. No local after-treatment is necessary. Of the forty-one cases seen in the hospital during eight years and diagnosed as retropharyngeal abscess, not one was fatal. One case, however—that reported in this article—was not diagnosed; the patient died, and was found to have been suffering from retropharyngeal abscess. A bibliography is given.

### 367. Treatment of Gastric Ulcer.

N. HORTOLOMEI (*Lyon Chirurgial*, September-October, 1923, p. 562), in discussing the surgical treatment of ulcers of the lesser curvature of the stomach, points out that surgeons are not in general agreement as to the best method to employ in such cases. Gastro-enterostomy, which is the easiest and simplest form of treatment, is not always found to be satisfactory. Resection of the ulcer is probably preferable and is practised by a number of surgeons at the present time. Resection necessarily entails the shortening of the lesser curvature and leaves the stomach as a deep sac lying low down, so that its emptying is accomplished both slowly and with difficulty. Gastro-pylorotomy, used for ulcers at the pyloric end of the stomach, has also been employed for ulcers at the lesser curvature, but it has the disadvantage of being

both a long and difficult operation. In annular gastrectomy the longitudinal muscular coat is divided, and this operation impairs the progress of the peristaltic waves at the site of the scar. To overcome these disadvantages Ostermeyer has carried out with success a form of longitudinal resection and plastic operation on the stomach combined with pyloroplasty. In this operation not only the ulcer but also a part of the anterior and posterior walls of the stomach are resected. The pyloric antrum is left as a canal a little wider than the duodenum. After the opening has been closed the lesser curvature is actually lengthened. The operation is easily performed after the separation of the lesser omentum and of the mesocolon if the posterior wall be involved. Curved clamps are applied along the lesser curvature and the ulcer excised. The opening is closed in the usual way by two layers of sutures. The author considers that this is the simplest operation for ulcers of the lesser curvature, and the stomach is found to empty itself rapidly afterwards. The re-forming of the lesser curvature by this method is an important feature which merits further consideration.

### 368.

#### Resection of the Bowel.

H. DOERFLER (*Zentralbl. f. Chir.*, October 6th, 1923, p. 1502) records two cases in which he resected unusually large portions of the bowel in 1917. The first was a man, aged 58, of good musculature, who developed a volvulus during strenuous physical exercise. The author operated thirty hours later, found the mesentery twisted through 180 degrees, and the small bowel extensively gangrenous. He removed practically the whole of the small bowel, leaving only 12 cm. of the jejunum and 20 cm. of the ileum, which were united by side-to-side anastomosis. The patient suffered severely at first from flatulence, required to be fed every two hours, and had an evacuation of the bowels every four hours. His condition gradually improved, and he now, six years after the operation, has the normal number of meals a day and only two evacuations of his bowels. It is stated that he leads an active life, his only complaint being that he tires a little more readily than he used to do. The second case is that of a woman who had a hugely dilated colon; the author resected the ascending and transverse colon, a length of 1 m. 22 cm. There was left of the large bowel 35 cm. only—the descending colon; the ileum was united to the descending colon by end-to-end anastomosis, both portions of the gut showing some dilatation. The patient made an uneventful recovery, and it is reported that she is to-day in good health with no intestinal symptoms.

### 369.

#### Teratoma of the Lacrymal Gland.

LLOYD B. WHITHAM (*Amur. Journ. Ophthalm.*, September, 1923, p. 757) describes a case of teratoma of the lacrymal gland. Tumours of this gland are rare, particularly teratoma. There are three general divisions of lacrymal gland tumours; first, solid tumours or neoplasms; secondly, cysts or dacryocysts, and last, symmetrical tumour-like enlargements due to Mikulicz's disease or lymphomata. In the present case the patient, a male 21 years of age, had noticed since the age of 5 years a large hair protruding from beneath the upper lid near the outer canthus of the left eye. This hair was cut off with scissors from time to time when it became troublesome. About a year ago he noticed a tumour lying in the left superior conjunctival fornix. Latterly this had been growing in size and had a reddish coloration. It had caused no symptoms. The tumour was large, pedunculated, multilobular, and of firm consistency, and latterly appeared to interfere with supraduction and abduction of the left eye. The tumour was removed easily by dissection. Subsequently the tumour was split with the scalpel and what appeared to be a small well formed tooth was exposed to view. The tumour was not cystic, but there was a fibrous lining inside of which there was a mass of spongy tissue suggesting a glandular structure. The tooth was embedded in this latter tissue.

### 370. Treatment of Hydatid Cysts of the Lung.

B. PERITCHITCH (*Paris Méd.*, September 15th, 1923, p. 214) records eighteen cases of hydatid cysts of the lung observed in patients aged from 12 to 51 at the hospitals of Sibenik, Zaza, and Split in Dalmatia from 1890 to 1923. In most cases he considers it best to refrain from operation. If the hydatid cyst is still closed and is very near the lateral surface of the lung, thoracotomy should be performed. But if the cyst is situated centrally or if the patient has just coughed up a cyst there is no need for interference. In the first case expectant treatment is indicated, and in the second case expectant treatment should be encouraged by the ordinary remedies for bronchitis, the patient being kept under observation so that an operation may be performed later if necessary, which is rarely the case.

## COCAINE AND ITS SUBSTITUTES.

BY

E. WATSON-WILLIAMS, M.C., CH.M., F.R.C.S.E.,

RESIDENTIAL SURGEON, H.M. PRISON, LONDON, AND LECTURER IN MEDICINE, UNIVERSITY OF BRISTOL.

### CONCLUSION.

With regard to legislation relating to drug addiction, let us have confidence in those experienced administrators who have charge of this aspect of the question. Let us be temperate in our desires for new legislation, remembering that too hasty legislation may do more harm than good. It is only by the steady method of advance, each step having been carefully thought out and considered in all its aspects, that true progress will be made.

Purely as a local anæsthetic, cocaine is probably unsuited for use, especially its toxicity, the varying susceptibility of individuals to its toxic action, and its instability. An endeavour has therefore been made to examine the evidence available from the clinical side on these points; and further, by experiment, to compare cocaine and some of its substitutes, particularly two recent introductions—bupivacaine and atoxodipine.

The toxicity of cocaine appears to be less than is frequently asserted. The evidence as to "idiosyncrasy" is scanty; and, especially in the most interesting cases of reported death from small doses, the accounts are so meagre as to preclude any chance of criticism.

### EVIDENCE OF REPORTED CASES.

The evidence of published cases was examined to discover if possible how far the alleged variable toxicity of cocaine is due to "idiosyncrasy" of the patients, and how far to varying methods of administration. Fifty fatal and many more non-fatal accidents were investigated. The total available references in the medical libraries of Bristol University and the Royal Society of Medicine extend over a period of about forty years. In a number of cases it was found that reports have been copied from one journal to another several times, often with loss of accuracy.

### Deaths Wrongly Ascribed to Cocaine.

Examination of the reports showed that of the fatal cases four seem to have been wrongly ascribed to cocaine poisoning. For example: (a) Dental infection, dose unknown; the patient became ill on the eighth day and died on the eleventh. "No mention or evidence of poisoning by cocaine." (b) Abadie's patient, aged 71, received two-thirds of a grain subcutaneously. She was considered at the time to have died of apoplexy (second attack). Neither time nor mode of onset of symptoms, nor appearance after death, correspond with cocaine poisoning.

### Dose of Cocaine Used in Fatal Cases.

The remaining cases include all those in which, though details are lacking, death was ascribed to cocaine poisoning. It is to be remembered that cocaine in the last century was used with a freedom and in a dose now uncommon. For example, one surgeon reports 1,600 operations in which injections up to 4 grains were given as a routine, with no serious accidents; another frequently injected over 1 grain in children, but under 5 years old; a third had alarming accidents among infants between 3 and 6 months old, from spraying or swabbing the fauces with 4 per cent. solution; a fourth

has become most extensive. The result that the illegitimate traffic of narcotics as to Morphin, Heroin, and Cocaine.

### 371. Prophylactic Vaccination against Pulmonary Infections before Surgical Operations on the Stomach.

O. GERNEZ (C. R. Soc. de Biologie, August-September, 1923, p. 660) records some interesting observations made at Professor Lambret's clinic in Lille, which, if subsequently confirmed, should be of considerable practical value. Numerous bacteriological examinations showed that most pulmonary complications following gastric operations were due either to the *B. pylori*—one of the proteus group—or to the enterococcus. Vaccines were made of each of these organisms, titrated to contain 500 million per cubic centimetre, and intradermal tests were made on the patient before operation. If there was a positive reaction it was concluded that the patient was susceptible to the organism concerned, and he was therefore actively immunized against it. After two or three injections a second intradermal test was made; if this was now negative, it was held to indicate that an immunity to it had been established. If it still remained positive a further series of injections was undertaken. By examining the antibody content of those patients who gave a positive reaction, it was found that there was an absence of antibodies to the organism in question, whereas in the case of those patients who gave a negative reaction, whether before or after vaccination, antibodies were present in the serum. Cases are cited in which the administration of vaccine sufficed to render a previously positive intradermal test negative, a change which was accompanied by the appearance of antibodies in the serum, where none had been present before.

## Laryngology and Otology.

### 372. Streptococcal Osteomyelitis of the Temporal Bone.

THE clinical picture of a disease of the temporal bone which may be recognized as a clinical entity is given by H. BOYD-SNEE (Journ. Amer. Med. Assoc., September 8th, 1923, p. 803). Of 285 cases the disease was found on both sides in 35. The findings in the pre-operative, operative, and post-mortem examinations made have been consistently characteristic in every case, and on the pathological and the bacteriological findings the specific diagnosis of acute streptococcal osteomyelitis rests. In 166 instances accurate pre-operative bacteriological findings were established culturally from the exudate recovered from the tympanic cavity. In every case but one attention was first attracted to the region by the development of an acute otitis media or an acute exacerbation of a chronic otitis media. In every instance the streptococcus was recovered from the tympanic exudate before the operation, and the same organism was again recovered, either in pure culture or in culture mixed with other pyogenic organisms, from the infected cancellous bone through the operation wound. The causal agents were found to be the streptococcus in mixed strains, or the streptococcus mixed with other pyogenic cocci (staphylococci and pneumococci) or bacilli (*B. influenzae*, *B. pyocyaneus*, and diphtheroid bacilli). The clinical picture of acute, uncomplicated, streptococcal osteomyelitis of the temporal bone is that of acute suppurative otitis media. The termination was fatal in 31 cases, making the mortality 11 per cent. The connexion between the primary osteomyelitis and terminal complication was definitely established by post-mortem findings in 24 cases. Two patients died of pneumonia which had no demonstrable connexion with the primary osteomyelitis. The streptococcus organism has been identified as a Gram-positive diplococcus, recovered from cultures from which the pneumococcus has been excluded by test, and was typed variously as *Streptococcus mucosus capsulatus*, *S. viridans*, *S. pyogenes*, *S. haemolyticus*, and *S. non-haemolyticus*.

### 373. Epistaxis from an Unusual Site.

BOENNINGHAUS (Deut. med. Woch., August 17th, 1923, p. 1038) notes that while the lower anterior part of the septum of the nose—Kiesselbach's area—is the most common site of recurrent haemorrhages from the noses of young delicate persons, there is a vein in another part of the interior of the nose to which haemorrhages may be traced in a few cases. The author gives the name of "vena lumen nasi" to this vein, which runs outwards from the septum of the nose to the alae nasi on, or just in front of, the low smooth ridge which marks the junction of the skin of the vestibule of the nose with its mucous lining. This vein is comparatively rare and when present is often overlooked because on rhinoscopy the nasal speculum pulls on it in its longitudinal axis, compressing it out of all recognition. This vein is sometimes visible only near the septum, but it may be as thick as a knitting-needle. The author calculates that he sees a case

of epistaxis from this source about once a year or every other year. In the position of this vein there is sometimes a fissure which has been started by scratching with a finger, and in the depths of this fissure the vena lumen nasi may be oozing blood. Cauterization of a bleeding vena lumen nasi is a more difficult undertaking than cauterization of a bleeding point in the septum of the nose which can easily be anaesthetized by the application of cocaine. In the former position cauterization is apt to be painful because the skin of the vestibule of the nose is comparatively refractory to the application of cocaine, and the operator must be careful to push the nasal speculum as close to the vein as possible so that the speculum intervenes between the thermo-cautery and the skin. It may even be advisable to anaesthetize the vestibule of the nose by an injection of novocain. The cause of epistaxis from this site is the same as that of epistaxis from the nasal septum—scratching with a finger.

### 374. Gradenigo's Syndrome.

LAPOUGE (Rev. de Laryng., Otol. et Rhinol., September 30th, 1923, p. 763) describes a case which showed this syndrome—acute otitis media, fronto-parietal headache, and paralysis of the sixth cranial nerve. A woman, aged 50, suffered from acute suppurative otitis media for which the membrane was incised. Frontal headache followed and persisted. A carious molar with an apical abscess was extracted and a maxillary sinusitis cleared up by lavage. The pain and the otorrhoea persisted and the headache grew worse. Five weeks from the beginning of the condition a cortical mastoid operation was done and a small subdural abscess over the tegmen atri was drained. The headache continued, and the wound after almost drying recommenced to discharge freely. About the sixtieth day of the disease a paralysis of the external rectus muscle of the same side was noticed. Diagnosis of simple petrous cellulitis was made and a radical mastoid operation performed. The condition improved for a time but became worse, and the wound, after almost drying, began to discharge again. Pain increased, the pulse and general condition rapidly deteriorated, and pus was seen to come from a fistula in the attic region. Further operation revealed an extradural abscess reaching to the Gasserian ganglion and from the petrous bone behind to the frontal lobe in front. The meninges were already infected, and after some aphasic symptoms the patient died of meningitis. Gradenigo's syndrome of symptoms usually indicates a simple cellulitis of the petrous bone and an oedema of the meninges which affects the sixth cranial nerve. This condition usually clears up after a cortical or radical mastoid operation. If, however, these symptoms persist or increase after such treatment much worse mischief is present, and a searching exploration must be made for petrous osteitis and subdural abscess, as these are the conditions almost certainly present.

## Obstetrics and Gynaecology.

### 375. The Prognosis of Heart Lesions during Pregnancy.

FROM the study of a number of cases of heart lesions in pregnant women, W. FREY (Zentralbl. f. Gyn., October 6th, 1923, p. 1553) concludes that the prognosis is not nearly so bad as is generally supposed, as only 2 per cent. of his cases died. This is probably due to the mortality given by other writers being only for bad cases and not for all classes of cases. He contradicts current opinion by stating that mitral stenosis gives a worse prognosis than aortic lesions due to sclerosis of the pulmonary arteries, whereas a greater tax is put upon the conducting power of the right ventricle; but even with mitral stenosis the prognosis is not bad, and the duration of life would appear to be longer than it is in cases of mitral insufficiency. The most dangerous time would seem to be the hours and days following delivery, owing to the blood collecting to a large extent in the pelvic vessels, with the result that the heart is incompletely filled, and thus its contractile energy is relaxed. The prognosis depends not so much on the nature of the cardiac lesion, however, but on the condition and conducting power of the cardiac muscle, complications of pregnancy also affecting the prognosis greatly. Pregnancy is always liable to give rise to a recurrence of an old endocarditis due entirely to mechanical conditions and not to septic complications. As regards treatment, cases of acute endocarditis should have pregnancy terminated at once, both in primiparae and multiparae, as pregnancy causes speedy development with severe damage to the myocardium. The diagnosis, which is of the greatest importance, is difficult, and the condition is often not diagnosed, but a rise of temperature, onset of anaemia, and, above all, tachycardia, should put one on the *qui vive*. Cases which show failure of compensation but no inflammatory changes should be treated conservatively by physical and

Summary.

Summarizing the above brief survey of 50 reported fatal cases of cocaine poisoning:

Death was not due to cocaine in	4
Death followed oral ingestion in	13
Death followed overdosage in	12
Dose was unknown in	12
Death followed employment of a dose stated to be	9
under 5 grains in	50

In the last class, in one case 4 grains was injected into the breast—clear evidence that the drug had very rapidly entered the general circulation. This appears to be the essential factor in all these cases.<sup>11, 12</sup> The circumstances of each case so far as they are known have been briefly considered.

Clinical Doses.

Judging from the published reports we may infer:

A. Fatal poisoning from clinical doses of cocaine is rare. "Idiosyncrasy" to cocaine in this sense is not established.

B. The lethal dose of cocaine for man by subcutaneous injection or by the mouth appears to lie between 12 mg. and 25 mg. per kilo, depending on the concentration.<sup>13</sup>

C. The same dose of cocaine in strong solution is much more dangerous than in weak.

D. For ordinary subcutaneous injections in dilute solution (1/4 per cent.), especially with adrenaline, the old "maximum dose" of 5 grains should be safe.

E. In vascular, including acutely inflamed, tissues, and other situations where the drug may rapidly enter the circulation, very great caution is necessary. This may apply particularly to injections for tonsil operations. (The intravenous lethal dose of cocaine for man has been estimated at about 1.5 mg. per kilo.<sup>14</sup> Cocaine has, however, been used intravenously.)

Other points which appear especially from the study of non-fatal cases (to which it has not been practicable to adhere in this paper) are:

F. Absorption from mucous surfaces is often rapid.

G. Accidents have become much less common since adrenaline has been in use. (Injection, however, of strong adrenaline into vascular tissue is itself a source of danger. Recent authorities advise 1 in 100,000 solution for injection, 1 in 10,000 solution for mucous surfaces.<sup>15</sup>)

H. It must be remembered that occasional severe and even fatal accidents have occurred with all the cocaine substitutes that have been extensively used.<sup>16</sup> The preliminary report of the American Committee on Toxicity of Local Anesthetics contains a table of recent fatal cases.<sup>17</sup>

Deaths	1	1	3	10	4	1	18	42
Alpin	1	1	3	10	4	1	18	42
Stovaine	1	1	3	10	4	1	18	42
Cocaine	1	1	3	10	4	1	18	42
Butyn and cocaine	1	1	3	10	4	1	18	42
Apobasin	1	1	3	10	4	1	18	42
Norocain and cocaine	1	1	3	10	4	1	18	42
Butyn	1	1	3	10	4	1	18	42
Cocaine	1	1	3	10	4	1	18	42

(a) Presumably injection of novocain after painting with cocaine.  
(b) Injection of butyn after painting with cocaine.  
(c) Fifteen of these included and analysed above.  
(d) See below, "Butyn."  
(e) This table possibly bears some relation to the frequency of use of the different drugs.

Stability of Cocaine.

Cocaine base in solution is said to be very unstable. The hydrochloride in moderately strong solution is stable, unless it becomes alkaline. A specimen, containing 1/2 per cent. of the same anesthetic power and toxicity as a fresh specimen. This same solution, although does had been taken from the bottle without precautions, was frequently sterilized. Cocaine hydrochloride can be sterilized by boiling.

administered 5 grains daily for months in one case,<sup>8</sup> 8 grains of 5 per cent. solution (5 1/2 grains) for urethral injection.<sup>9</sup> Fatal and even serious accidents from clinical use seem, however, from the available published reports to have been rare.

Oral Ingestion.

In 13 cases death was due to taking a large dose by the mouth.<sup>18-30</sup> The smallest fatal doses were: (a) about 10 grains taken by a woman—it might have been more;<sup>18</sup> (b) 12 grains in 10 per cent. solution taken by a girl;<sup>19</sup> a man survived 9 grains solid;<sup>20</sup> and others 10 grains, 22 grains, and it is said 46 grains, diluted.<sup>21</sup> One patient took at least 60 grains daily for months, but died when she took 20 grains in one dose.<sup>22</sup>

Subcutaneous Injection.

Six cases died after subcutaneous injection. In 5 a definite overdose was given—namely, 20, 19, 17, 12, and 8 grains respectively.<sup>23-27</sup> Injection of 4 grains into the breast caused death.<sup>28</sup> Doses of 18, 15, and 14 grains (in 55 per cent. solution) were

Twelve cases of death are reported following subcutaneous injection.  
In 4, owing to carelessness, strong solutions were injected instead of weak—for example, 20 per cent. instead of 0.2 per cent.; the victims recovered, therefore, one hundred times the intended dose. In 4 more the dose was not known. In the remaining cases the doses were (a) 20 minims of 1 per cent. solution in adrenaline 1 in 1,000; (b) 2 drops of 2 per cent. solution (=1/50 grain); (c) 1/4 grain (= 1 1/2 grains of cocaine); (d) 2 drachms of 0.2 per cent. solution in adrenaline 1 in 1,000 (= 2 grains of cocaine). It seems hardly credible that the injected cocaine alone caused death in (a), (b), (c), and (d) the dose of adrenaline injected was too high for safety. In none of these cases is mention made of painting the tissues before injection; if this were done the cocaine absorbed may have largely exceeded the doses given; details of all are scanty. In each case death occurred almost at once, showing that the drugs reached the general circulation very rapidly. (It is noteworthy that injections for tonsil operations account for a number of fatal accidents with several anesthetics, even dilute novocain; the painting before injection has perhaps received too little attention in some cases.) One death followed injection of 10 per cent. solution of cocaine into the nasal septum in mistake for 1 per cent.<sup>29</sup> Two deaths followed injection of 1 per cent. solution of cocaine into the nasal septum in mistake for 1 per cent.<sup>30</sup> In one case 1 1/2 grains injected for rectal fistula operation caused death in four minutes.<sup>31</sup> Injections for haemorrhoids caused convulsions with 5 grains and 3 grains, and less serious trouble with several doses of this order.<sup>32</sup>

Injection into Cavities.

Death followed injection of 6 grains in 5 per cent. solution into a recent hydropoe. It was considered that "this relatively feeble dose," safe in chronic hydropoe, was in this case rapidly absorbed by the unthickened tunica vaginalis. Injection into the recently wounded urethra was responsible for three deaths—doses, 5 grains,<sup>33</sup> 2 1/2 grains, and 1 grain.<sup>34</sup> Death in each case occurred in a few minutes. Absorption, however, from the intact urethra is rapid.<sup>35-37</sup> 7 grains caused convulsions.<sup>38</sup>

A dose of 22 grains injected into the rectum caused death in a few minutes.<sup>39</sup> (The surgeon committed suicide.)

Surface Absorption.

Application of 4 per cent. solution to abraded skin caused death in a few minutes.<sup>40</sup> Four fatal accidents followed application to the fingers; doses unknown.<sup>41</sup> In another case death followed the application of 20 per cent. solution to the larynx.<sup>42</sup>

Numerous accidents, mainly not very serious, are reported in connection with the application of 10 per cent. or stronger solutions (without adrenaline). Further in 1891 pointed out that absorption from the nasal mucosa was particularly rapid. In this connection it is worth remembering that the addition of one type, who spares neither pains nor ingenuity, has discovered that application of solid cocaine to the nasal mucosa is the most rapid, efficient, and economical method of introducing a toxic dose into his cerebral circulation.

psychical rest, diet, and digitalis, strophanthin intravenously, being of use in cases of threatening insufficiency, in addition to the digitalis given orally, and squill is probably better for long-drawn-out cases, as it is not so cumulative. If improvement does not occur termination of pregnancy is advised. In fully compensated cases with no inflammation termination of pregnancy is not required. General sterilization of patients for whom pregnancy has been terminated artificially is not advised, for in the majority of cases healing occurs and the power of conduction is restored. All cases of mitral stenosis should be carefully watched, especially those which are rapidly advancing, as they are the most dangerous.

### 376. Treatment of Retained Placenta.

T. R. GOETHALS (*Amer. Journ. of Obstet. and Gynecol.*, September, 1923, p. 322) quotes Polak and also Bumm as reporting a mortality of 10 per cent. after manual detachment of the placenta. In 170 cases in which this procedure was carried out at the Boston Lying-in Home the mortality was 8.2 per cent., but after deducting cases in which death might be attributed to other morbid conditions of labour the rate was 1.8 per cent. One case in four of hospital patients in whom the placenta was delivered manually and two in five of out-patient deliveries showed post-partum uterine infection, which, however, was as a rule of a mild type. In cases of placental retention without haemorrhage the Gabastou-Mojon method of injection of warm saline solution into the placenta through the umbilical vein has, in the experience of many writers, proved successful in averting manual removal with its high mortality and morbidity. Definite indications for removal by hand are found (1) in profuse haemorrhage, (2) when one or more cotyledons are missing from the placenta after its expulsion, (3) when a retained placenta is inexpressible even under an anaesthetic, after a certain period of waiting which is given at from two to twelve hours in the practice of various clinics. An important danger attending manual extraction is that "placenta accreta" may be encountered, and it is impossible to foresee the existence of this condition, in which there is a lack of the normal spongy layer of the decidua, and infiltration of the degenerated uterine muscle with chorionic villi; consequently the placenta is so blended with the uterine wall that no line of cleavage is discernible. Practically all recorded cases of "placenta accreta" have proved fatal from haemorrhage and shock, the majority with some portion of the placenta still retained. In cases in which manual extraction is impossible or so difficult as to lead to diagnosis of "placenta accreta" Goethals recommends an intrauterine pack as an emergency measure, followed by abdominal hysterectomy.

## Pathology.

### 377. Physiology of the Pineal Body.

THAT the chief function of the pineal body is to prevent premature development of the male and female sexual organs is the conclusion arrived at by Y. IZAWA in the course of experimental work (*Amer. Journ. Med. Sci.*, August, 1923, p. 185). This observer performed the operation of pinealectomy on a series of 36 young fowls, at the same time using 11 others as observation controls. Only 4 birds survived the operation for any length of time (3 male and 1 female), and these were fed under similar conditions to the control animals. All were killed 130 days after operation. At first the pinealectomized group appeared to be retarded in growth, but about a month after operation began to develop more rapidly than the controls. The cocks commenced to crow prematurely and showed an early development of comb compared with the animals not submitted to the operation. On autopsy the testes were abnormally large, and microscopically the seminiferous tubules were much dilated, containing several layers of epithelial cells presenting all degrees of spermatogenesis, whilst those of the controls were small and almost filled with a few layers of undifferentiated epithelium. In the case of the single pinealectomized female that survived till it was killed, the ampullary portion of the Fallopian tube was greatly developed; section of the ovary showed well developed follicles about three times the size of those in the control females. Other endocrine organs presented slight or no difference in the pinealectomized and control specimens. The author notes that, in the main, his findings correspond to those of other observers quoted, and reference is also made to two published cases occurring in man, where in the one instance overdevelopment, and in the other incomplete development, of the pineal body produced, respectively, retarded and increased activity and growth of the organs of sex.

### 378. The Complement Fixation Reaction in the Diagnosis of Bovine Tuberculosis.

BROCC-ROUSSEU, A. URBAIN, and CAUCHEMEZ (*Ann. de l'Inst. Pasteur*, September, 1923, p. 872) have conducted a research on the value of the complement fixation reaction in the diagnosis of tuberculosis in cattle. The blood was collected from the heart of the animal after it had been slaughtered; the serum thus obtained was used for the reaction, which was conducted according to Calmette's and Massol's technique using Besredka's antigen. Altogether the serums of 203 cattle, proved at autopsy to be suffering from tuberculosis, were examined; the serums of 74 animals shown macroscopically at autopsy to be free from tuberculosis were included as controls. Of the former group no fewer than 94.09 per cent. gave a positive fixation reaction; of the latter only 1.36 per cent. were positive. In order to investigate the reason why 12 of the animals shown to be tuberculous gave a negative reaction, cultures on Petrof's medium and injections into guinea-pigs were made of the lesions of 6 of these. It was found that in 3 of these cases the lesions were sterile. In other words, the disease was no longer active. As a point of interest it was noticed that animals suffering from tuberculosis which had received an injection of tuberculin showed a higher quantity of antibodies in their serums than those animals which had not been tested with tuberculin. From this research the authors conclude that, setting apart hypertrophic enteritis, the complement fixation reaction in cattle is specific and can be applied to the diagnosis of bovine tuberculosis.

### 379. The Destruction of Foreign Blood Cells in Rabbits.

IT has been stated that certain iron-containing endothelial cells of the spleen in rabbits are responsible for the destruction of foreign red blood cells. To ascertain if this were so F. L. PICKOF (*Journ. Infect. Dis.*, September, 1923, p. 230) injected 5 c.cm. of a 50 per cent. saline suspension of washed chicken corpuscles intravenously into eight rabbits. Blood films made at successive intervals showed that the foreign cells disappeared from the circulation in forty to sixty minutes without, however, any appreciable haemolysis being noticeable. In another series the rabbits were killed at varying intervals of fifteen minutes to four hours after the injection, and histological preparations were made of the various organs. Examination of these demonstrated an accumulation of the chicken cells in the capillaries of the liver, spleen, and marrow, where they were destroyed within three to four hours after injection. This destruction was definitely extracellular, only a small number of nuclei and no whole cells being found in the Kupffer cells of the liver. Since the weight of the liver in the rabbit is about seventy times that of the spleen, and as in the microscopical preparations about an equal number of foreign cells were found per field in each of these organs, it may be concluded that the liver is of much greater importance in the destruction of those cells than the spleen. Moreover, it was found that in rabbits on which splenectomy had been performed the disappearance of the injected chicken cells from the circulation and their destruction in the organs pursued a normal course. What the actual mechanism of the destruction is, must be left open to conjecture.

### 380. The Brain in Dementia Praecox.

S. KURE and M. SHIMODA (*Journ. of Nerv. and Mental Dis.*, October, 1923, p. 338) report on the macroscopical anatomy of the brain in 106 cases of dementia praecox among the Japanese—the first item in a detailed study of the serology, pathology, experimental treatment, and clinical observation of the disease. Kraepelin's new classification of dementia praecox has been adopted, but excluding paraphrenia. The weight of the brain in this series is compared with that of normal and diseased Japanese brains. The average brain weight of the male dementia praecox is 1,322 grams, the normal 1,378 grams, the general paralytic 1,293 grams, and the idiot 1,294 grams. In the female the dementia praecox brain averaged 1,170 grams, the normal 1,239 grams, the general paralytic 1,184 grams, and the idiot 1,133 grams. The degeneration is confined to the cerebral hemispheres, which decrease in weight as the dementia advances, while the weight of the rhombencephalon is unaffected. In rather more than half the cases the cerebral hemispheres were equal in weight. Gyrus atrophy is noted in 88.6 per cent. of the cases, the frontal lobe being involved in 7.5 per cent., the parietal in 55.9 per cent., and the temporal in 31.8 per cent. Clinical features of interest in the series are: (1) the average age—40.7 years; (2) the average duration of the disease—12.5 years; (3) the age group of greatest mortality—third and fourth decades; and (4) the causes of death—pulmonary and intestinal tuberculosis accounting for about 45 per cent. of the cases, beri-beri and nephritis coming next with a mortality of 11.5 per cent. and 8.5 per cent. respectively.

The influence of adrenaline was investigated in a hyper-minimal lethal dose of anaesthetic; (b) in separate sites. For example: solution of cocaine hydrochloride containing 1.5% of cocaine = 110 mg. per kilo. Result: Death in nine minutes. Dose of cocaine = 4 per cent. of 1 in 5,000 adrenaline lowers the toxicity of cocaine. With strong solutions of anaesthetic not well shown. Other anaesthetics are being investigated and may deduce the toxicity of cocaine. The effect of applying these anaesthetics to mucous membrane was examined by gently swabbing the nasal passages of rabbits. On the other hand some of the solution was swallowed. This could be used, or the drug got blown out. The following abridged protocol is given:

Comparative Toxicity. Experimental investigation is proceeding; these notes indicate briefly the results so far obtained.

A. To what extent does the safety of these anaesthetics vary with (1) concentration of drug; (2) manner of administration; (3) presence of adrenaline?

B. Why do experimental and clinical estimates of comparative toxicity differ?

C. Has the answer to B a bearing on the application of experimental results to clinical work?

D. What is the experimental toxicity of butyn and atoxodine?

These notes indicate briefly the results so far obtained; experimental investigation is proceeding.

Comparative Toxicity. The lethal dose by subcutaneous injection, as an example, the following abridged protocol is given:

No. 50—Rabbit, 1.95 kilos; injection of 0.95 c.c.m. of 20 per cent. solution of alpin = 190 mg. = 98 mg. per kilo.

Weakness of limbs, coarse twitching. Urgent dyspnoea, pupils dilate. Lying on side, weak convulsion. Flaccid paralysis. Condition improving. Later the animal was quite normal.

Result: Severe toxicity; recovery. Severe toxicity; recovery. Very severe toxicity; recovery. Death in ten minutes. Death in eight minutes.

Therefore the M.L.D. = 45 mg. per kilo. Having thus determined the M.L.D. for each animal, with each drug, using the same concentration of each drug with toxicities can be made and expressed as a fraction of the toxicity of one, say cocaine, taken as the standard. Of course, the higher the M.L.D. the lower must be the toxicity.

Comparative Experimental Subcutaneous Toxicities.

Alloxodine ... M.L.D. = 80  
Butyn ... M.L.D. = 100 mg. per kilo.  
Stovaine ... M.L.D. = 110 mg. per kilo.  
Novocaine ... M.L.D. = 120 mg. per kilo.

The effect of concentration was investigated—for example, 20 per cent. solution ...

A further variation when these limits are exceeded, and similar result with novocaine and alpin, is indicated by experiments not yet complete. Butyn does not appear so much influenced in its effects by concentration of the injected solution.

\* For this my thanks are due to Professor I. Walker Hall

Experiments are being made in the Pathological Laboratory, with cocaine, novocaine, stovaine, butyn, and atoxodine.

The particular questions, among others, to which an answer is sought, are:

To what extent does the safety of these anaesthetics vary with (1) concentration of drug; (2) manner of administration; (3) presence of adrenaline?

Why do experimental and clinical estimates of comparative toxicity differ?

Has the answer to B a bearing on the application of experimental results to clinical work?

What is the experimental toxicity of butyn and atoxodine?

The influence of adrenaline was investigated in a hyper-minimal lethal dose of anaesthetic; (b) in separate sites. For example: solution of cocaine hydrochloride containing 1.5% of cocaine = 110 mg. per kilo. Result: Death in nine minutes. Dose of cocaine = 4 per cent. of 1 in 5,000 adrenaline lowers the toxicity of cocaine. With strong solutions of anaesthetic not well shown. Other anaesthetics are being investigated and may deduce the toxicity of cocaine. The effect of applying these anaesthetics to mucous membrane was examined by gently swabbing the nasal passages of rabbits. On the other hand some of the solution was swallowed. This could be used, or the drug got blown out. The following abridged protocol is given:

Comparative Toxicity. Experimental investigation is proceeding; these notes indicate briefly the results so far obtained.

A. To what extent does the safety of these anaesthetics vary with (1) concentration of drug; (2) manner of administration; (3) presence of adrenaline?

B. Why do experimental and clinical estimates of comparative toxicity differ?

C. Has the answer to B a bearing on the application of experimental results to clinical work?

D. What is the experimental toxicity of butyn and atoxodine?

These notes indicate briefly the results so far obtained; experimental investigation is proceeding.

Comparative Toxicity. The lethal dose by subcutaneous injection, as an example, the following abridged protocol is given:

No. 50—Rabbit, 1.95 kilos; injection of 0.95 c.c.m. of 20 per cent. solution of alpin = 190 mg. = 98 mg. per kilo.

Weakness of limbs, coarse twitching. Urgent dyspnoea, pupils dilate. Lying on side, weak convulsion. Flaccid paralysis. Condition improving. Later the animal was quite normal.

Result: Severe toxicity; recovery. Severe toxicity; recovery. Very severe toxicity; recovery. Death in ten minutes. Death in eight minutes.

Therefore the M.L.D. = 45 mg. per kilo. Having thus determined the M.L.D. for each animal, with each drug, using the same concentration of each drug with toxicities can be made and expressed as a fraction of the toxicity of one, say cocaine, taken as the standard. Of course, the higher the M.L.D. the lower must be the toxicity.

Comparative Experimental Subcutaneous Toxicities.

Alloxodine ... M.L.D. = 80  
Butyn ... M.L.D. = 100 mg. per kilo.  
Stovaine ... M.L.D. = 110 mg. per kilo.

Why do experimental and clinical estimates of comparative toxicity differ?

Has the answer to B a bearing on the application of experimental results to clinical work?

What is the experimental toxicity of butyn and atoxodine?

1883 De Dion Bouton 1924

THE WISDOM OF AN EARLY SELECTION.

*If you ordered your De Dion Bouton Car now it would be ready for Jan. 1st—the new licensing period. It would contain all those welcome details that you miss—and grumble about to-day. It would be a weatherproof car. It would be built to fit your driving stride: trimmed to your liking, and painted with your chosen colour. The engine and chassis are noted for their endurance. Also they are economical and speedy. 4-wheel brakes are fitted as standard to the 3 Models that have Overhead Valve Engines. Withal for such high quality the prices are extremely low.*

*Our Agents will take your present car in part payment, or arrange payment from income terms: Complete cars from £540.*

May we send you further particulars?

De Dion Bouton, Ltd., 10, Gt. Marlborough St., London, W. 1.

# BISHOP'S SOLUBLE ASPIRIN IN TABLETS

Registered Name

# LITMOPYRINE

*Each Tablet contains 5 grains of Lithium Acetyl Salicylate.*

PERFECTLY SOLUBLE IN WATER.

**LITMOPYRINE TABLETS DO NOT UPSET THE STOMACH.**

ANTIPYRETIC, ANALGESIC, DIAPHORETIC:

**INDICATIONS:—Muscular and Articular Rheumatism, Polyarthritides, Sciatica, Gout, Lumbago, Influenza, and all Feverish Conditions, Colds, Catarrhs, Bronchitis, Headaches and Neuralgia.**

*BOTTLES containing 100 Tablets 4/6 post free. Also supplied in powder form and as a Granular Effervescent. Samples and Descriptive Literature sent free to Medical Men by the Sole Manufacturers of Litmopyrine.*

**ALFRED BISHOP, LIMITED,** Manufacturing Chemists, 48, Spelman St., London, E. 1.

\* Cocaine was printed on fauces in one case.

two were examined at later dates and both remained free from discharge, one after ten weeks and the other after four months. Three cases in which a slight discharge persisted were afterwards treated by zinc or copper ions and the discharge disappeared. These cases were seen again after two, three, and six months respectively, and no discharge was visible. In the remaining six cases the patients said that the discharge had diminished. In these the discharge was not purulent in appearance, and in one it was clear and resembled mucus. In one of the two cases in which gonococci were not found before the diathermy the discharge disappeared after the treatment; the patient was told to report again but did not do so. The other case could not complete the treatment as she had to leave London; her doctor reported that the discharge was "much less." The patient from whom the gonococci could not be made to disappear was probably reinfected as her husband also had gonorrhoea and was under treatment at the centre.

The question whether complete cure of gonococcal cervicitis or urethritis has been obtained cannot be answered by the absence of gonococci from the discharge. Complete subsidence of discharge is in its favour. Often, however, some discharge continues, and the question will arise in such cases whether the discharge is pathological. A discharge of pure mucus is not evidence of gonococcal infection. If, however, pus is present in the discharge it must be considered as pathological. A point in the treatment will often be reached in which although the discharge is mainly mucus there are still present small numbers of leucocytes. After ionization and diathermy in which sloughing has taken place leucocytes will be present as the result of the formation of granulations. Often, on the cessation of treatment, these will disappear and the discharge will finally clear up after a short time without further treatment. It is to be remembered that these treatments to the cervix *tend to maintain* this muco-purulent discharge. It becomes therefore a matter of judgement founded on experience when the treatments should be left off in the expectation that the discharge will eventually cease.

#### *Treatment of Gonococcal Prostatitis by Diathermy.*

At present we have not obtained sufficient evidence to enable us to make a definite conclusion on the action of diathermy on gonococcal prostatitis. Our results so far seem to show that the new treatment possesses therapeutic action in this disease. We treated one of our cases of arthritis by applying diathermy to the prostate only, and obtained the effects already mentioned—namely, abolition of pain, reduction of swelling, and increase of movement. We also noted the disappearance of pain and tenderness from the epididymis in a case of gonococcal infection of this part after application of diathermy to the prostate only. The following case also is suggestive. The patient gave a history of gonorrhoea. In his perineum there was a fistula leading to his urethra immediately behind a stricture of the passage mentioned. He complained of severe pain in the right lower limb. There was tenderness on pressure over the back of the thigh and flexion of the hip caused extreme pain. It was decided to apply diathermy to the prostate only. Complete and permanent relief of pain was produced, and the only symptom which remained was some discomfort on stooping with the knees extended.

It has already been mentioned that some of the cases of arthritis did not obtain relief until the urethra and prostate were also subjected to diathermy. In all these cases, save that described above, both prostate and urethra were treated simultaneously. We are therefore unable to state the region on which the diathermy exerted its therapeutic action—whether the urethra or prostate or both. Further light on this question would be thrown by the application of diathermy to cases in which only the anterior urethra was infected and to others in which the clinical evidence pointed to subsidence of infection from the anterior urethra with persistence in the prostate. This investigation is at present occupying our attention.

## DIATHERMY FOR MALIGNANT DISEASE OF THE MOUTH, PHARYNX, AND NOSE.

WITH NOTES ON SEVENTEEN SUCCESSFUL CASES.

BY

NORMAN PATTERSON, M.B., CH.B. EDIN.,

F.R.C.S. ENG.,

SURGEON, THROAT AND EAR DEPARTMENT, LONDON HOSPITAL.

For the last eight years I have been employing diathermy in the treatment of carcinoma affecting the mouth and pharynx. Unfortunately, the great majority of the patients treated were suffering from advanced disease; this was true of all the early cases, and of nearly all those treated in hospital. A very considerable number of patients were suffering from secondary deposits in the glands on one or both sides of the neck, and in some cases the glandular involvement was extensive. Cutting operations of magnitude had, therefore, frequently to be carried out in the neck; diathermy is rarely, if ever, of any use in dealing with the malignant extensions in the neck. Faulty technique and the too timid use of the diathermy electrode accounted for some of the failures in the earlier series of cases. Owing to the great size or unfavourable position of the growth, or the general cachectic condition of the patient, many of the cases dealt with would now be deemed unsuitable for any sort of treatment. Haemorrhage during the separation of the sloughs was a not infrequent occurrence. Since I have adopted ligature of the main vessel or vessels supplying the part in cases requiring extensive diathermy, or in patients with thickened arteries and high blood pressure, severe haemorrhage has not been met with.

When the growth is small, superficial, and situated some distance from important and vital structures, and when the glands are free from involvement, or only slightly invaded, there is an excellent chance of a complete and lasting cure. My experience is that, if local recurrence is going to take place, it will generally happen during the first six months. This, of course, does not apply to recurrences in the neck. When the primary growth is very extensive, deeply rooted, and situated in a locality unfavourable to its free destruction, and more especially when the secondary deposits in the neck are massive or fixed, there is little likelihood of effecting a cure, and there may be great risk in subjecting the patient to operation. However, most of the cases recorded in this article were described by others as "inoperable," and some of them were very extensive; it is difficult, therefore, to draw the line between cases which should be subjected to treatment and those which should be left alone. Much depends on the general condition of the patient and the special experience of the surgeon. Every practitioner should be alive to the grave significance of an ulcer or indurated area occurring in the tongue, mouth, or pharynx of a patient over middle age. The condition rarely proves to be simple, or due to any other cause than malignant disease. It is well, therefore, to regard every doubtful case as one of cancer until it is proved to be due to some other cause. To the practised observer the diagnosis of epithelioma is generally easy. Over and over again the author has seen patients who have been diagnosed as suffering from "septic ulcer," "cyst," "gumma," when the real trouble was epithelioma. Many cases of supposed syphilis are repeatedly injected with salvarsan or soaked with iodides. It is important to remember that a great many patients with buccal or pharyngeal cancer will give a positive Wassermann reaction.

In the majority of cases the growth is visible on ordinary inspection—it is generally best to use reflected light. If it is situated at the base of the tongue, low down in the pharynx, or in the neighbourhood of the larynx, a laryngeal mirror will be required for its inspection. In nearly all cases palpation with the finger is possible, and it should never be omitted, as the cartilaginous hardness of an epithelioma is one of its most characteristic features.

Microscopic examination of a fragment of the tumour

will clinch the diagnosis. There is one objection to this method—namely, that even such a small operation is especially the case if some of the surrounding healthy tissue is removed at the same time. Before removing a portion for microscopic examination, consent should, therefore, be obtained for an early operation, should such an operation be found to be necessary.

So far the only treatment of cancer which has stood the test of time is that which aims at the total removal or destruction of the tumour and its extensions. The writer has come to the conclusion, after considerable experience, that in cancerous growths situated in the pharynx and mouth the ultimate results are likely to be infinitely better when the primary growth is dealt with by diathermy, rather than by a cutting operation. He stated (Lancet, 1920) his reasons for this opinion, which he has had no cause since to modify. Many brilliant successes would be obtained if the disease could only be diagnosed and treated in its early stage.

The glands have not been removed in every case; this is owing to the fact that consent has not always been obtained. Removal of glands (and this generally means thorough clearance of both anterior and posterior triangles by "block" dissection) should be carried out even when no enlarged glands can be discovered on palpation. In one of the author's cases—not recorded in this series because he has a recurrence—a man suffering from a small epithelioma involving the uvula, and just extending on to the soft palate, was treated by diathermy. There was no enlargement of the glands, but the patient was urged to have the triangles of the neck cleared out on both sides. He abso-

lutely refused. Four years later malignant glands have developed on both sides of the neck; the region of the palate has remained perfectly healthy. It is generally advisable to destroy the growth in the first instance, and subsequently to remove the glands. Occasionally the two operations can be carried out at the same sitting. If the surgeon is in doubt whether or not he can make a thorough clearance of the neck, then the gland operation should precede that on the primary growth. If the glands cannot be dealt with it is little use applying diathermy to the primary tumour, except as a palliative measure. It is sometimes advisable to operate on the glands in the first instance, and to deal subsequently with the primary tumour, as consent for the neck operation may be difficult to obtain after the growth itself has been destroyed. Before commencing treatment it is well to try and obtain consent for two or three operations, and to impress on the patient the importance of the removal of glands. If the diathermy area approaches or invades the fascial planes of the neck—and this is most likely to occur in cancer of the floor of the mouth—a clear interval of a fortnight or three weeks should be allowed between the destruction of the primary growth by diathermy and the neck operation. If this rule is not observed alarming sepsis may occur in the neck, which may lead to a fatal issue. Preliminary ligation of the external carotid should be adopted, as stated above, when secondary haemorrhage is to be feared.

The following cases have been successfully treated. In some of these it might almost be stated that a cure has been effected; in most of them it is to be hoped that the disease will not recur.

*Case 1.* A man complained of sore throat, and on examination there was discovered an extensive epithelioma of the right tonsil and side of the tongue and of the floor of the mouth. This was treated by diathermy, and the patient went on well for a time. Later, however, he returned to hospital with a canceromatous tumour involving the right side of the tongue and the right sub-maxillary region. The tumour in the mouth was subjected to a major diathermy, and the mass in the neck was removed by dissection. The patient, nearly eight years later, is actively engaged as a tram conductor and at present there is no sign of growth.

*Case 2.* An elderly lady was found to be suffering from endothelioma of the base of the tongue. With the aid of suspension laryngoscopy the growth was removed by diathermy (excision method). There was no recurrence six years after operation.

*Case 3.* A man, aged 52, complained of soreness of the floor of the mouth and lump at the right side of the jaw, of two months' duration. On examination a carcinoma of the middle of the floor of the mouth was found; the tongue was freely movable, and there was an enlarged hard gland in the right sub-maxillary region; the glands on the left side were not enlarged. The growth was freely destroyed by diathermy, and a fortnight later the glands were removed in the usual way. There was no recurrence more than six years after.

*Case 4.* A woman, aged 53, presented a cauliflower-like growth (epithelioma) on the right side of the hard palate, and on transillumination the right anterior maxilla was dark. The upper jaw was resected, and three weeks later the cavity was thoroughly subjected to diathermy. The patient went on well for a year and ten months, when she reappeared with a small nodule in the scar, which was destroyed by diathermy. Six months later she came to hospital with a large mass in the upper part of the neck, which was removed, together with the neck and glands in both anterior and posterior triangles, the internal jugular vein, and the upper portion of the sternomastoid muscle. She is well six years and three months after the original operation.

*Case 5.* A man, aged 55, complained of soreness of the throat, of seven weeks' duration; there were enlarged glands on the left side of the neck. An epithelioma of the posterior part of the tongue on the left side was found, invading the anterior part of the fauces and the tonsil. The growth was removed by diathermy, and the glands were removed in the usual way. There was no recurrence four years and five months after operation.

*Case 6.* A man, aged 57, complained of pain on swallowing for several months; he was an excessive smoker, but a total abstainer. Examination showed a large epithelioma of the right tonsil and palate, which was removed by diathermy. A year later the glands on the right side of the neck were thoroughly removed. There was no recurrence four years and five months after operation.

*Case 7.* A man, aged 46, had suffered from repeated sore throat during the previous three years, and six weeks before he was examined he began to have pain on swallowing; he had lost weight during the past year. On examination an extensive carcinoma of the base of the tongue, right tonsil, and soft palate was found. Diathermy was applied to the growth, and a fortnight later an extensive removal of the glands on the right side of the neck was performed, and the external jugular vein resected. A fortnight later, again, the glands were cleared on the left side of the neck, and at the same time diathermy was applied to a small area of growth which had been missed at the first operation. A month later a suspicious area was seen and diathermy was applied to it. There was no recurrence three years after the last operation.

*Case 8.* A man, aged 67, had a small superficially placed epithelioma of the left tonsil and anterior pillar; there was no enlargement of the glands. The growth was thoroughly destroyed by diathermy. Three months later a hard gland was discovered by the situation of the left carotid. The anterior triangle was dissected, and three months later a hard gland was removed by diathermy. The growth was thoroughly destroyed by diathermy. There was no recurrence after the first operation.

*Case 9.* A middle-aged lady had an epithelioma of the posterior pharyngeal wall, just above the arytenoids. Suspension laryngoscopy was employed to bring the growth into view, and it was destroyed by diathermy, together with a good margin of the surrounding tissue. After three years there was no recurrence.

*Case 10.* A man, aged 64, had noticed a small lump on the left side of his tongue for four months. Examination showed an epithelioma of the tongue and floor of the mouth; no glands were palpable. Diathermy was employed, and the tongue was divided down the centre and cut across well behind the growth. There was no recurrence two years and three months after operation.

*Case 11.* The patient, a man, had noticed a hard lump on the right side of the tongue for two or three months. On examination an epithelioma of the tongue and floor of the mouth was found; no glands were palpable. The growth was removed by diathermy, and a fortnight later the anterior triangle of the right side was cleared. Six weeks later the glands were removed from the left side of the neck. There was no recurrence two years after diathermy.

*Case 12.* A man, aged 72, had noticed "a little bladder" on the roof of the mouth for six weeks. He was a moderate smoker (wooden pipe). An epithelioma of the roof of the mouth was found on examination; there were no enlarged cervical glands. The growth and its surroundings were thoroughly destroyed by diathermy, and there was no recurrence one year and ten months after operation.

In so far as chronic ulcer is concerned these figures are of only very limited value. The important point is to know the age at which gastric ulcer commences, and that, obviously, is a thing very difficult to determine. Most of the chronic ulcers in this series gave a history going back several years, many of them fifteen or twenty years. Perhaps if all the figures for chronic ulcer were moved back a decade, the result would not be far from the truth.

With regard to sex, my own figures show that chronic gastric ulcer occurs with slightly greater frequency and chronic duodenal ulcer six times more frequently in men than in women. Sir Berkeley Moynihan's (1923)<sup>23</sup> clinical statistics show that chronic gastric ulcer occurs with equal frequency in the two sexes, and chronic duodenal ulcer four times more frequently in men than in women.

### C. MORBID ANATOMY AND HISTOLOGY.

[The lecture was illustrated with photographs of gross specimens, and with a series of histological sections mounted on lantern slides.]

On morbid anatomical grounds, both naked-eye and microscopic, it is possible to subdivide the ulcers of the stomach, and to a less extent those of the duodenum, into acute, subacute, and chronic varieties. The chief grounds of histological differentiation are the presence or absence of fibrosis, whether in the floor or in the margins of the ulcer, and, if present, its amount and characters. In the separation of non-inflamed acute ulcers and callous non-reacting chronic ulcers this may be almost the only distinguishing feature, but in active ulcers there are other histological criteria. An active acute ulcer in all but the earliest stages shows a zone of neutrophil polymorphic infiltration in its floor, sometimes extending a considerable way downwards from the necrotic surface. This is often accompanied by a certain amount of oedema, especially of the submucosa. It must be remembered, of course, that chronic ulcers are liable to acute exacerbations, which usually take the form of localized activity at a certain point or points of the margin or floor. Such foci will show neutrophil polymorphic reaction, but it will be superimposed on an obviously chronic lesion, and will not be so uniformly distributed as in acute ulcer.

In addition to fibrosis, chronic ulcers nearly always show foci of lymphocytic infiltration, usually in relation to small blood vessels. A certain number of plasma cells may be mixed with the lymphocytes, but these cells are not usually abundant except sometimes in the mucosa and submucosa at the margin. Infiltration of the floor of subacute and chronic ulcers by eosinophil leucocytes is common, and in a few cases reaches a high grade of intensity. Even in acute ulcers a few eosinophils may be present, but they are seldom conspicuous.

The state of the vessels in the floor of an ulcer, and beyond it, may be of help in differentiating acute and chronic. In acute ulcers the small vessels implicated in the disintegrative process are often seen to be filled with thrombi or fibrinous plugs, and even vessels of larger size may be so affected, especially if they have been ulcerated into. This is often found—for example, in cases where there is a history of haemorrhage a few days before death. In the floor of a chronic ulcer similar changes may be found, but in addition there is often well marked endarteritic and endophlebitic thickening, due to intimal proliferation. Sometimes this is associated with thrombotic obliteration of the remainder of the lumen, and sometimes with complete organization and canalization of the thrombus. Similar vascular changes are often seen on the peritoneal aspect of gastric scars.

#### 1. Acute Ulcers.

These are usually multiple, especially in the stomach. In a series of 46 cases of acute gastric ulcer, 6 only were single. Both in stomach and duodenum they tend to be widely and irregularly distributed, with the exception that in the stomach they are usually most abundant in the pyloric half. They vary in size from tiny superficial erosions of the mucosa to large and deep ulcers measuring an inch or more in diameter. The great majority, however, are under half an inch in diameter, and most are under a quarter of an inch. In general it may be said that the more numerous the ulcers the smaller their size. I am convinced that there is no

dividing line between what have been called multiple haemorrhagic erosions and acute ulcers of larger size.

Acute ulcers are usually described as presenting a punched-out appearance, and this is equally true of both large and small varieties. As regards depth, most acute ulcers, and practically all multiple small ones, are quite shallow, confined to the mucosa, or at most the mucosa and submucosa. In the earliest stages, as seen in the *post-mortem* room, there may be almost no excavation, a quite superficial necrotic lesion with slightly reddened margins being situated on a very slightly raised and thickened patch of mucosa. Later, as the ulcer deepens, tiny vessels are exposed in the floor, which then very frequently becomes covered by a thin black layer of altered blood, or of slough infiltrated with blood. Later still, preparatory to healing, the black slough separates, leaving a clean smooth floor, in which all haemorrhage has ceased, as a result of thrombotic obliteration of the little exposed vessels. In the duodenum the slough in the floor of acute ulcers may be black and haemorrhagic, as in the stomach, but if not it tends to be bile stained. Here also there is often slight oedematous thickening around and beneath the ulcer.

Acute ulcers of larger size which are tending to penetrate the stomach wall present the well known "terraced" appearance, due to the fact that the muscular coat is penetrated over a smaller area than that occupied by the original mucosal ulcer. If the peritoneal coat should perforate, this again usually takes place over a still smaller area, and a third step is added to the terrace. The perforations in the various coats may be concentric or excentric. In my experience acute perforating ulcer of the stomach is rare. In 6,800 autopsies there were but 8 examples, of which 6 proved directly fatal—3 by perforation, 2 by haemorrhage, and 1 by mesogastric cellulitis.

Acute ulcers tend to heal readily, and if they involve only the mucosa and submucosa may do so without leaving a permanent scar. If the muscular coat is involved a certain amount of fibrosis will take place therein and a permanent scar result. In acute penetrating ulcers which heal—probably a very rare event—the permanent scar in the muscular coat will be visible from the peritoneal as well as the mucosal aspect. In a certain proportion of cases one ulcer, rarely more, fails to heal with the rest, persists, enlarges, and becomes first subacute then chronic.

#### 2. Chronic Ulcers.

In the stomach chronic ulcers are almost invariably single. In a series of 150 cases coming to autopsy there were only 3 in which two independent chronic ulcers co-existed. It is not uncommon, on the other hand, for a chronic ulcer to be accompanied by one or more acute ulcers, a fact which is of importance in relation to the well known recurrent character of the symptoms in these cases. In the duodenum double chronic ulcer, anterior and posterior, is fairly common. In a series of 200 cases coming to autopsy there were 32 with double ulcers. Here also acute and chronic ulcers may coexist.

The position of chronic gastric ulcer is well recognized. The great majority occur along the lesser curvature or in close proximity to it, and especially in the pyloric three-fifths. On the other hand chronic ulcer is rarely seen exactly on the pylorus, and it is by no means common within an inch of it. I have analysed a series of 125 cases coming to autopsy in which the exact position of the ulcer was noted, and find that no less than 90 per cent. occur along the course of the original gastric canal.

In considering the duodenum it has been thought advisable to take both ulcers and scars into account. In 1,500 autopsies there were 74 cases with chronic duodenal lesions, all within the first part of the viscus—namely, 23 with anterior wall ulcers or scars, 18 with posterior ulcers or scars, and 33 with double lesions. In practice it was found that invariably the ulcer or scar was wholly or mainly on the anterior or posterior wall, although large posterior wall ulcers were not infrequently found to have extended on to the superior or inferior wall or both. It is in these circumstances that perforation of a posterior wall ulcer is most likely to occur.

Chronic ulcers, especially of the stomach, are usually a good deal larger than the acute variety. In a series of 40 chronic gastric ulcers 17 were under 1 inch and 8 over 3 inches in diameter. In a corresponding series of duodenal ulcers 29 were under 1 inch and 11 from 1 to 2 inches in diameter.

The naked-eyed characters of a chronic ulcer vary very much according to the state it happens to be in at the time of examination—that is, according to whether it is active, callous, or healing. As compared with acute, chronic ulcers have thickened, rounded, and overhanging margins in the active state. In callous ulcers the margins are flatter, though still often undercut, while the healing ulcer has flattened margins, with the epithelium in most cases obviously growing inwards over the floor. In the active ulcer a narrow zone of sloughing with inflammatory exudation is almost invariably present in the floor, sometimes in patches, sometimes all over. It shows up as a narrow yellow or reddish-yellow line when the fresh ulcer is cut across, and in histological preparations it stains deeply. Microscopically it consists of an intensely eosinophilic structureless groundwork, with a zone of darkly staining nuclei, or nuclear debris, in its more superficial part. In places these are obviously the nuclei of polymorph leucocytes; elsewhere they are apparently pyknotic tissue-cell nuclei. In chronic ulcers which are the seat of an acute exacerbation this necrotic or necrosing layer is very broad and irregular, and beneath it the tissues of the ulcer floor are often much infiltrated by neutrophil polymorphs. The separation of the slough is a necessary preliminary to the healing of the ulcer, as Bolton has pointed out, its presence being an effective barrier to epithelialization. Ulcers in which ingrowing of marginal epithelium can be observed have always a clean smooth floor, at least in relation to the healing part. Callous ulcers resemble healing ulcers in this respect. Either the floor is clean and fibrous, or there is a very narrow zone of necrosis without much cellular reaction.

One of the most constant features of a chronic ulcer, whether of the stomach or duodenum, is penetration of the muscular coat. I have never seen a chronic ulcer in which the muscularis was not completely transgressed, although occasionally one of subacute type may only partially involve it. Perforation is prevented mainly by the great fibrous and granulation tissue barrier formed in the floor, less often by adhesions between the stomach and some adjacent viscus—pancreas and liver especially. Pads of fat, more or less fibrosed, are commonly found in the floor of gastric and duodenal ulcers. In the stomach this is seen chiefly in lesser curvature ulcers, where the fat is merely the adipose tissue of the gastro-hepatic omentum. In the duodenum, ulcers involving the posterior wall or encroaching on the upper or lower walls show it, not anterior wall ulcers as a rule. In other cases the pad of fat may be due to adherent omentum or to retroperitoneal tissue in the lesser sac to which the ulcer has become adherent. On the other hand, it is not uncommon to find both chronic ulcers and scars totally devoid of any such fatty mass on the peritoneal aspect.

Large ulcers of great chronicity may be associated with so much inflammatory thickening in and around them that a palpable tumour may be present in the epigastrium leading to an erroneous diagnosis of cancer. Even at operation it may be difficult, sometimes impossible, to distinguish. As a rule, however, the peritoneal aspect of a simple chronic ulcer is fairly characteristic. There is thickening and opacity of the serosa as a result of fibrosis and oedema, together with vascular congestion, often intense, and not infrequently areas of haemorrhage in cases where the ulcer is active. White radiating lines of fibrosis run out from the margins of the ulcer, and there is often a vascularized fibrous band of adhesion to some adjacent structure. The floor may show fine reddish stippling owing to the presence of numerous small, thin-walled vessels in the new-formed fibrous tissue, an appearance which may be brought out at operation by gently stroking the part with gauze (Scudder). In old, completely scarred ulcers the stippling, congestion, and haemorrhage disappear and the floor of the scar becomes white and sclerotic, and may show puckering. The

shape of the ulcer crater also varies. In the stomach, in active ulcers of medium and moderately large size, it is usually deep and globular, or deep with a flat floor. Smaller ones are often similar, or may be slit-like, the mucosal margins almost meeting across the lesion. Very large ulcers, and especially callous ulcers, tend to be flat, with low, often undermined edges, and a smooth floor. Such ulcers are very frequently of the "saddle" variety, lying across, and at right angles to, the lesser curvature of the stomach. In these, as in very large posterior wall ulcers, whether gastric or duodenal, a part of the floor is usually formed by the pancreas. Healing ulcers, whether large or small, also tend to flatten out as marginal epithelialization progresses.

#### D. HEALING OF GASTRIC AND DUODENAL ULCER AND ITS RESULTS.

The process of healing (Stewart, 1922<sup>11</sup>) is similar in acute and chronic ulcers. Following the cleaning up of the floor of the ulcer—that is, the separation of sloughs or purulent material, and the disappearance of bacteria—the epithelium at the margin starts to grow inwards, while at the same time, especially in chronic ulcers, the contraction of the fibroblasts in the floor causes the ulcer to become reduced in size. Acute ulcers heal rapidly, chronic ulcers much more slowly, not only because of their larger size, but also because of the large amount of dense fibrous tissue in their floor. At the same time there can be no doubt that even very large and very chronic ulcers may heal completely, while chronic ulcers of smaller size heal with very considerable frequency. The results of healing depend on several factors, especially the size of the ulcer, its chronicity and its situation. Ulcers related to the pylorus, whether primarily gastric or duodenal, need not be of large size to produce cicatricial stenosis. In the body of the stomach ulcers of small and medium size usually heal satisfactorily; it is only large ulcers which produce serious mechanical defects (hour-glass stomach). In the duodenum, ulcers within half an inch of the pylorus frequently implicate it, and those situated lower down lead to duodenal stenosis in a small proportion of cases. In a recent series of 29 cases with completely healed scars of chronic gastric ulcers—that is, scars involving the whole thickness of the muscular wall—21, or 72 per cent., had healed satisfactorily without resulting stenosis. The figures for duodenal ulceration and scarring are similar. Even if a chronic ulcer heals completely, there is always the possibility of a new chronic ulcer making its appearance in another part of the stomach. My own statistics show that this will occur in about 9 per cent. of cases.

There are two other ways in which the recurrent character of chronic peptic ulcer may be explained. It may be due to breaking down of the old scar, a process of which it is very difficult to adduce proof, or it may be due to chronic ulcer becoming callous and quiescent, with subsequent recrudescence of ulcerative activity. Of this, both surgeons and pathologists can bring forward convincing proof.

#### E. COMPLICATIONS OF PEPTIC ULCER.

The more important complications of chronic gastric and duodenal ulcer are indicated in the accompanying analysis of 350 fatal cases (p. 1024).

##### 1. Perforation.

Perforation is the most serious and one of the most common complications of both gastric and duodenal ulcer. On the other hand, the figures given in the table are obviously no index of its frequency in all cases, since the great majority of perforated ulcers are admitted because of this accident. This swells unduly the proportion of perforated cases in these statistics.

Perforation takes place rapidly in the great majority of cases by the sudden sloughing of a part or of the whole of the peritoneal floor of the ulcer, this in turn resulting from a slow, progressive devascularization. The aperture, therefore, is usually of considerable size, from one-eighth to a quarter of an inch in diameter, and it is easily seen at operation, if in an accessible position, unless concealed by

of his care, cases of post-prostatectomy vesiculitis are frequently overlooked. Once this condition is established it is but a matter of time before the inflammation spreads to the testicle.

This further complication usually occurs within a few weeks of the onset of vesiculitis, but as long an interval as three months may elapse. It is a common experience that the patient will return with an attack of orchitis although his immediate consciousness appeared to be satisfactory. Local treatment of the testis, such as fomentation, to subside, but no guarantee against a further recurrence of the inflammation can be given so long as a nidus of infection persists in the seminal vesicle.

In a recent article in the *Lancet* Winbury White has drawn attention to the frequency of epididymitis as a complication of prostatectomy. Studying 50 cases from the records of St. Peter's Hospital he found that 82 per cent. gave evidence of inflammation of the testicle, and tabulated the degrees as follows:

1. Thickening of the epididymis.
2. This change is more marked.
3. The epididymis becomes adherent to the testis and its coils adhere to one another.
4. The epididymis becomes large, hard, and firmly fixed to the testis. The change as a rule is more marked in the globus minor.
5. The testis may become tender.
6. The testis may be tender.
7. The testis may be tender.
8. The testis may be tender.
9. The testis may be tender.
10. The testis may be tender.

These observations make it clear that the patient's general state of health can remain seriously impaired, although he has submitted himself to prostatectomy.

Since Freyer popularized the operation of suprapubic prostatectomy it has been the aim of surgeons to improve upon the original technique in order to minimize the risk of complications, but only slight success has rewarded their efforts. The explanation lies in a recognition of the difficulty of preventing the kidneys, damaged by back pressure, from excreting a urine loaded with colon bacilli. Since prevention is better than cure, we can endeavour to avoid vesiculitis and orchitis by urging our patients to submit themselves to prostatectomy before bacilluria has occurred. But should bacilluria be present the attempt must be made by the methods outlined by me in a recent article in the *Journal of Clinical Research* to cleanse the urinary conduit before the operation of removal of the gland is undertaken. However, this is not always possible, and so the surgeon must introduce some technique at the time of operation to limit the spread of infection from the bladder to the seminal vesicles, and thence to the testicles.

It has been suggested that following the excision of the gland, the vesiculae might be removed by dissection, but personally I am of opinion that such further prolongation of the operation as this would entail (and also taking into consideration the poor state of health and possibly advanced age of the patient), would cause the mortality rate of suprapubic prostatectomy to rise immediately.

The infection of the seminal vesicles can be prevented by ligation of the ejaculatory ducts, and in certain selected cases I have adopted this procedure; but the difficulty of ligating these small ducts, when the tissues around the base of the bladder are constantly bathed in blood, will produce the same result as may be expected from removal of the seminal vesicles by dissection.

As the isolation of the seminal vesicles from infection is so problematical we must consider what steps can be taken to prevent it spreading to the testicles. I have found that by dividing the vas deferens below the external abdominal ring I can guarantee to my patients that whatever other complications they may get they will never suffer from epididymo-orchitis.

The technique is simple, and in less than five minutes both vasa can be isolated and divided. After having removed the prostate and closed the wound of the anterior abdominal wall I feel for the vas among the other constituents of the spermatic cord through the skin of the upper part of the scrotum. I then hold it firmly between my finger and thumb immediately beneath the skin.

Having next made a small incision a quarter of an inch long, the vas deferens can be picked up with a pair of toothed forceps and pulled out of the wound. The part of duct thus exposed is freed from the loose cellular tissue which surrounds it and divided between two catgut ligatures. It is not necessary to remove a piece of the vas for the purpose. The two ligated ends are pushed back into the wound, which is closed by a single suture of catgut. Assistant is doing the same on the other.

Not so long ago it was taught that when the vas deferens is cut atrophy of the testicle will follow. This is an entirely erroneous observation. I have carried out the technique just described on every case of prostatectomy, both in hospital and private practice, for the past two years, and not in a single case has the testicle wasted. Moreover, there is no loss of sexual appetite and no inhibition of the act. Nor have I experienced any failure to prevent orchitis. The result of this small operation proves that infection from the region of the prostate spreads to the testis along the vas, and not by way of the blood stream. It also demonstrates that the lymphatic duct, since in a few cases I have had to open an abscess under local anaesthesia at the point where I had divided the vas, the infection having spread along the duct, where its further progress was blocked by the dissolution of continuity at the external abdominal ring.

## SECTION OF PATHOLOGY AND BACTERIOLOGY.

HEEN MARRAS, M.D., D.Sc., M.R.C.P., President.

### DISCUSSION ON THE VALUE OF SEROLOGICAL TESTS IN DIAGNOSIS.

#### OPENING PAPER

H. R. DEAN, M.A., M.D., OXON., F.R.C.P.,  
Professor of Pathology, University of Cambridge.

The serum reactions which take place *in vitro* between antigen and the reactions which take place *in vivo* understand, as I think, the reactions which take place in the body. The serum reactions which take place in the body are understood, as I think, the reactions which take place in the body. The serum reactions which take place in the body are understood, as I think, the reactions which take place in the body.

§ One died from haemorrhage from the ulcer and one from leakage and peritonitis.

plastic exudate or adhesions. In the stomach the perforation is usually on the anterior wall and close up to the lesser curvature. In the present series of 150 cases 58 were perforated. In 81 per cent. of these the perforation was on the anterior wall, in 15.5 per cent. on the posterior, and in 3.5 per cent. on both. In the duodenum perforation is even more common. It was present in 122 cases out of 200 which came to autopsy, and in the great majority of these it was an anterior wall ulcer which had perforated. Of the anterior wall ulcers 80 per cent. had perforated, and of the posterior only 9 per cent.

The results of perforation vary with the size of the aperture and its position, and according to whether or not the stomach is empty at the time of the catastrophe. The rapid extravasation of a large quantity of stomach contents through an anterior wall perforation will result in a rapidly fatal peritonitis. The slow oozing of infected material allows time for a certain amount of limiting plastic peritonitis to occur, and the peritoneal abscesses so formed may track in various directions, up under the liver or diaphragm, including abscesses due to perforation into the lesser sac, or down into the lower abdomen or pelvis. Such localized abscesses may rupture into the general peritoneum at any stage, or, rarely, they may perforate into pleura or pericardium, through the anterior abdominal wall, or into an adjacent hollow viscus.

## 2. Haemorrhage.

Though much less frequent than perforation as a cause of death, this remains, in its severe form, one of the most serious complications of gastric and duodenal ulcer. In fatal cases the bleeding is generally found to originate in a chronic ulcer, and very often the open end of an artery may be seen in the floor. In the present series of 6,800 autopsies 33 deaths from ulcer were due to haemorrhage. In 13 of these the ulcer was gastric (12 chronic, 1 acute); in 20 duodenal (19 chronic, 1 acute). In the stomach it is usually a branch of the coronary artery, or the splenic or gastro-epiploic artery, which is the source of the haemorrhage, in

the duodenum the pancreatico-duodenal. In a few cases the haemorrhage comes from some adjacent viscus, liver and spleen especially, which has been penetrated by the ulcer. In the duodenum profuse haemorrhage is almost invariably due to ulcer of the posterior wall; in the stomach to ulcer of the posterior wall or lesser curvature. When bleeding is profuse there is usually haematemesis, irrespective of whether the blood is of gastric or duodenal origin, and melaena makes its appearance very soon after. If the bleeding is slight, melaena without haematemesis will result.

## 3. The Development of Malignant Disease.

The relation of gastric ulcer to carcinoma is one of the problems on which there is greatest diversity of opinion. Most pathologists consider that cancerous transformation of a simple chronic gastric ulcer is comparatively infrequent (Ewing, 1918,<sup>22</sup> suggests 5 per cent. as a maximum figure), most British and American surgeons that it is a very common event (54 to 71 per cent. according to the Mayo Clinic—Mayo, 1908,<sup>23</sup> Wilson and McCarty, 1909<sup>24</sup>). No doubt on this point *post-mortem* observations are apt to be fallacious, for the reason that the destructive effects of cancer of the stomach by the time the patient has come to autopsy may be such that the original simple ulcer has become completely destroyed. My own conclusions therefore are drawn from operation specimens only, and of these I have microscopically examined 120. The histological criterion on which ulcer-cancer cases was decided was the association in the same ulcer of an undoubted area of carcinoma with a portion which was definitely simple, and whose densely fibrous floor, devoid of cancer cells, replaced the muscularis. Suffice it to say that 10 per cent. of the cases of simple chronic ulcer coming to operation had developed cancer in the ulcer, and that in one-half of these the malignancy was unsuspected at the time of operation. Most cancerous ulcers of the stomach are, in my experience, primary cancers which have undergone central ulceration, and not simple ulcers which have become malignant.

The extraordinary rarity of duodenal carcinoma in contrast to the high ulcer incidence has long been the subject of comment, and it is often quoted as evidence against the view that chronic ulcer bears an important etiological relationship to carcinoma of the stomach. In the present series of 6,800 autopsies there were 150 cases of cancer of the stomach and only one case of primary carcinoma of the duodenum.

## 4. Jejunal Ulcer.

This serious and important complication of the operation of gastro-enterostomy has been of comparatively infrequent occurrence hitherto. A recent estimate by Sir Berkeley Moynihan (1923)<sup>25</sup> is that the incidence does not exceed 2 per cent., but it seems likely that further experience may show a higher figure. In the present series of 6,800 autopsies there were 16 cases in which gastro-enterostomy had been performed at periods varying from nine months to twelve years before, and in 3 of these jejunal ulceration was present. In 18 cases where an interval of from ten days to two months had elapsed since the operation, there was one case of jejunal ulceration. In each of these 4 cases the original operation had been for duodenal ulcer, and this is in keeping with clinical experience. The fact is no doubt related to the much greater degree of hyperchlorhydria present in this disease. In two of the cases death was directly attributable to the jejunal ulcer.

Jejunal ulcers may be acute or chronic, single or multiple, and they are similar in their naked-eye and microscopic characters to peptic ulcers of the stomach and duodenum. They are most common on the convexity of the jejunal loop—that is, at a point directly opposite the gastric stoma—or in the first inch or so of the efferent channel. They also occur not infrequently on the gastro-jejunal suture line—gastro-jejunal ulcer. They may cause death by perforation or haemorrhage, and apart from a fatal issue may be responsible for a return of gastric symptoms, often in an

tion, and of recent years little has been added to our knowledge.

Not does it appear that the intensive study of practical methods of diagnosis which has prevailed during the last

fifteen years has yielded results of very great importance.

Progress there has been; improvements of method and improvements in details have led to greater accuracy and to

some extension of previously known methods to diseases for

the diagnosis of which serum methods had hitherto not been

employed. The old methods still stand out—the agglutina-

tion or Vidal reaction for the recognition of infections

produced by the typhoid bacillus and its near relatives,

and the complement fixation reaction for the diagnosis of

syphtis. These two reactions, the Vidal and the Wassermann

man reactions, stand out in a position of respectable isolation,

for, in spite of much work, efforts to extend the agglutina-

tion and complement fixation reactions to the diagnosis of

other important infectious diseases do not appear to have

been crowned with success commensurate with the amount

of work which has been done.

The remarkable specificity which obtains in the reactions

which take place between antigen and antibody was observed

during the progress of the earliest work on the serum

reactions. Almost every year has added something to our

knowledge of the exquisite differentiation between closely

related substances which these reactions can enable us to

detect. The specific affinity of antigen for antibody and

the nature of the specific, chemical, reaction

which underlies and is the cause of the demonstrable pheno-

mena which we call serum reactions, remains to-day as great

a mystery as ever. To review the problems arising from

this specificity of antibodies is to review the whole subject

of immunity, and I must select one particular aspect

of specificity for consideration to-day. What does the

specificity of the serum reactions signify? What is the

meaning of a difference demonstrable by a serum reaction

between two cultures of bacteria which when compared by

any other method appear to be both morphologically and

culturally identical? Does a serological difference between

two cultures, unsupported by any difference demonstrable by

any other means, justify us in the conclusion that we have

to do with two separate species? Or are we to consider an

unsubstantiated serological difference as evidence of variation

or mutation within one species? Are serological differences

of more significance than morphological differences or such

physiological or cultural differences as can be elicited by the

examination of the capacity of a particular micro-organism

to ferment a series of test sugars?

A new light on the specificity of the serum reactions has

been cast by the work recently published by Andrews. It

is well known that if a rabbit is immunized by injections of

a culture of some member of the Salmonella group, *B.*

*acetylicae, for example, the resulting serum may agglutinate*

not only the homologous bacillus but also its near relatives.

Such a serum is said to contain a mixture of specific

and group agglutinins. Andrews took a pure culture of

*B. paratyphosus* O and placed it out. Subcultures were

made in broth from ten separate colonies. These ten sub-

cultures were tested with a specific paratyphoid O serum

(a serum from which group agglutinins had been removed)

and against a serum rich in group agglutinins (which had

been prepared by injecting an animal with a culture of a

nearly allied member of the Salmonella group). Five of the

subcultures were agglutinated practically to full titre by the

specific paratyphoid serum and failed to agglutinate with

the group serum. The other five cultures were slightly

affected by the pure serum but agglutinated by the other

group serum to about one-third of the full titre for the

homologous strain. That is to say, the colonies on the plate

were of two different kinds and apparently of two different

kinds only. As each must be considered as the product of

a single bacillus it follows that a pure culture of a micro-

organism contains individuals of different kinds, and these

differences can be demonstrated by a serum reaction.

Andrews attempted to cultivate the two types as separate

entities. At times he succeeded in obtaining two successive

broth cultures in which the character was maintained pure,

but far more commonly even the second broth culture showed

a mixture of types.

It is evident, therefore, that serum reactions can be made

to demonstrate variations occurring in the individuals com-

prising the population of a pure culture. It is evident that

the differentiation which can be effected by a serum reaction

goes a great deal further than the differentiation of one

species from another. It is, of course, very difficult to define

what we mean when we use the word species in relation to

the bacteria. There are many named and described varieties

within the Salmonella group. These can be differentiated

with varying degrees of difficulty by their behaviour on

sugar media and by the type of disease which they produce

as well as by their serum reactions. It seems difficult to say

what degree of difference or what combination of differences

would justify us in speaking of a distinct species. On the

other hand, bacteria apparently so distinct from one another,

as the meningococcus and the gonococcus appear to have a

great similarity in antigenic structure. Indeed, experienced

serological methods from the gonococcus from the meningococcus.

If micro-organisms which we should all regard as belonging

to different species may contain antigens which have so

much in common with one another and if the individual

in pure culture of a strain of *B. acetylicae* are liable

to such profound spontaneous variation in their antigenic

structure, it seems obvious that we yet have much to learn

as to the significance of the sharp differentiation which we

are able to effect by means of serological methods.

Another example of the ultra-specific analysis, which sero-

logical methods allow us to carry out, is provided by the

is-*agglutinins* for blood corpuscles, by the help of which we

may divide mankind up into four groups. Here, again, is

matter of great biological interest. By serological methods

we are able to distinguish very subtle differences between

individuals. Moreover, it seems that the transmission of

these characteristics from parent to offspring can be shown

to follow the accepted principles of heredity.

An extreme example of specificity was brought to my

notice during the later years of the war when the majority

of wounded men received four and often more prophylactic

doses of tetanus antitoxin, and it was to be expected that

in a few cases symptoms of anaphylaxis might occur. Cases

in which serious symptoms occurred were very few, but

it sometimes happened that in one hospital and during one

week several mild cases were reported. Thinking that such

cases might be due to some peculiarity of the particular

brand of antiserum, R. S. Adamson and I obtained speci-

mens of serum from these patients. We used the patients' various

serum and used as antigens various

separations of pneumococci and meningococci into groups

of strains produced by these two varieties of bacillus. The

value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

not identical. The value of this delicate differentiation is

aggravated form. Rarely they perforate into the transverse colon with resulting gastro-colic fistula.

## SECTION OF SURGERY.

Sir HENRY M. W. GRAY, K.B.E., C.B., C.M.G.,  
F.R.C.S. Edin., President.

DISCUSSION ON  
THE TREATMENT OF ACUTE PRIMARY  
INFECTIONS OF THE HAND.

## INTRODUCTORY PAPERS.

I.—D. P. D. WILKIE, O.B.E., M.Ch., F.R.C.S. Edin.,  
Assistant Surgeon, Edinburgh Royal Infirmary.

THE importance of this subject, whether viewed from a medical or from an economic standpoint, can hardly be exaggerated, and I can imagine no better subject for discussion at a meeting such as this. Here we deal with the wide problems of infection, resistance, and immunity; we endeavour to crystallize our views on the principles governing our treatment of infection in both its general and local aspects, and withal, we deal with a subject of everyday importance to the practitioner of medicine. In hospital practice there is often an unfortunate tendency to regard infections of the hand as belonging to the realm of minor surgery, to be dealt with by the less experienced members of the staff; yet no cases present more difficult problems for decision, and not infrequently the life of the patient may depend on the line of treatment which is adopted. The majority of such infections are met with in the robust, wage-earning class of the community, and the difference between the rapid restoration of a hand to early and full function and the prolonged, tedious, and crippling course of the neglected or maltreated case is one of far-reaching economic import.

In the first place we must look at certain fundamental pathological considerations. The introduction of pathogenic micro-organisms into the tissues is followed by certain reactive changes, both general and local. The response by fever with its heightened metabolism, the increase in the circulating phagocytes in the blood stream, and the production of antibodies we recognize as part of Nature's effort at protection. At the seat of infection we find a reactive hyperaemia, an outpouring of lymph, and an aggregation of phagocytic cells—a local endeavour to destroy or wall off the invading germs and prevent their entrance into the blood stream. We now regard these changes as essentially protective, and we endeavour to aid and to reinforce them by such means as we possess. We know, however, that in the hand in particular the outpouring of lymph and the death of many of the phagocytes is apt to lead to an accumulation which, in certain areas, is limited as to available space, so that dangerous tension may ensue and the vascular supply and the vitality of the part may be threatened. Further, the concentrated toxins of the infecting bacteria, together with the proteolytic ferment liberated from the dead and dying phagocytes,

tend to the death and liquefaction of the surrounding tissue cells. From such an area there will be absorption of the bacterial toxins and proteoses which will have a profound and deleterious influence on the bodily economy.

The sphere of active surgical interference is the provision of drainage of such areas of suppuration and tension, and that before irreparable damage has occurred. It is essential, therefore, that we have clear ideas as to the types of infection met with, and, in the case of the suppurative variety, the sites at which pus is liable to accumulate and the routes by which it may spread.

Following on extensive inflammation, and especially on that associated with suppuration, is the inevitable fibrosis, fixing tendons, binding muscles, stiffening joints, compressing nerves and vessels, so that a limb may be helplessly crippled in every constituent part of its functional apparatus. It is essential that we bear this in mind when we are in doubt as to the necessity for what seem to be ruthless incisions. The disability following an unnecessarily extensive incision is as nothing compared to that following a burrowing, liquefying, and prolonged suppuration. Moreover, in our after-treatment it is of paramount importance to anticipate and to prevent the fixation of mobile parts by unyielding fibrous tissue, and to remember that the preservation of tissue without function is a mere waste of time and energy.

## ANATOMICAL CONSIDERATIONS.

Certain points in the anatomy of the hand and digits have an important bearing on the course and spread of infection. First, the lymphatic network in the hand is very full and free, particularly on its palmar aspect, whence lymphatic trunks come to the forearm, mainly by way of the dorsum.

Secondly, the cellular tissue is divided into spaces by septa which serve to localize or guide the spread of infection. In the pulp of the digits—that is, the soft part on the palmar aspect of the terminal phalanges—dense, fibrous septa, extending down to the periosteum of the phalanx, enclose the fatty tissue, and infection of this tissue leads to great tension with necrosis, which is very apt to involve the bone. In the palm of the hand we have the deep cellular spaces so clearly demonstrated by Kanavel, of which the two most important are the middle palmar and the thenar spaces. Situated deep to the dense palmar fascia and the long tendons, and just in front of the interosseous muscles, a collection of pus in the former space will point along the lumbrical muscles of the third, fourth, and fifth digits; in the thenar space it will tend to point to the radial side of the index finger. A knowledge of the existence and the boundaries of these spaces will enable us to recognize and drain a collection of pus in either or both of them before irretrievable damage has been done to the hand.

Thirdly, the tendon sheaths have an anatomical arrangement which, although not constant, is sufficiently regular and well known to require no elaboration here. An accumulation under tension in a tendon sheath will, besides endangering the vitality of the enclosed tendons, tend to rupture either into one of the palmar spaces or, in the case of the little finger and thumb—the ulnar and radial carpal bursae—into the deep cellular planes of the forearm underneath the flexor communis digitorum. In the fingers these tendon sheaths have such intimate relationship to the first interphalangeal joints, that infection of these joints is a common sequel to an infective teno-synovitis.

samples of antitoxin and specimens of normal horse serum obtained from the slaughterhouses. From one patient who had shown marked signs of shock we obtained a serum which reacted with dilutions of the antitoxin which had been used to inoculate him and formed with this antitoxin a well marked precipitate. The same patient's serum when mixed with similar dilutions of a normal horse serum produced only a faint trace of precipitate. We then performed the converse experiment and tested an antihorse serum which we had obtained from a rabbit after injections of horse serum, against dilutions of normal horse and against dilutions of antitoxin. In this case marked precipitates were found in the tubes containing the normal horse serum and only traces in the tubes containing antitoxin. Subsequently we immunized a series of rabbits with different specimens of horse serum obtained from individual horses and also with specimens of antitoxin obtained from various strains and laboratories. The antitoxic sera were, of course, usually mixtures derived from several horses. My complement fixation methods it was possible to show well marked differences between individual horses and between various brands of antitoxin. Our material was, of course, insufficient for any attempt at grouping the various sera according to their antigenic value. It seems possible that by a sufficiently extended series of experiments a definite grouping of horses might be effected. Members of each group might be utilized for antitoxin production and by the use of a series of antitoxic sera derived from horses whose serum showed well marked serological differences, the dangers attendant on repeated inoculations of antitoxin might be reduced. Another example of extreme specificity is provided by the antibody formation which follows the injection of extracts or emulsions of particular organs. There is some evidence that a specific antibody can be produced by the injection of the proteins or antigens of the lens of the eye. It is evident that here we have to deal with the differentiation of single organs within an individual. Dale's experiments on anaphylaxis afford another example of extreme specificity. By the use of the guinea-pig uterus method Dale has shown antigenic differences between the protein fractions of one and the same sample of serum. If, as some maintain, the difference between the various fractions into which serum proteins may be separated depend largely on physical differences, differences in the state of molecular aggregation, rather than on differences of chemical composition, it is evident that the interpretation of the significance of the specificity of the serum reactions may lead us in new and unexpected directions.

It seems to me that it is worth while to pause and consider what a positive serum reaction means. In typhoid and allied infections the significance of a positive reaction is purely diagnostic. It tells us that the patient has had an inoculation of typhoid vaccine. In the case of the Wassermann reaction, if you will admit that a positive Wassermann reaction depends on the presence of an antibody, there is, in addition to the diagnostic, a therapeutic interest. In a case of declared syphilis we are pleased if by treatment we can convert a positive into a negative reaction. If, later on, the positive reaction returns we may predict a return of symptoms of active disease. On the other hand, there are many cases of syphilis in which the disease has been latent for twenty years, in which a strongly positive reaction may be present in the serum of a man who appears to be in perfect health. It is related that a woman who had borne syphilitic children may never show any sign of active disease and yet when examined years after the presumed date of infection may be found to have a strongly positive Wassermann reaction. The complement fixation reaction in cases of gonorrhoea, still to be established, has been put to a significant use. In long-standing cases of this disease, it is notoriously difficult to determine the period during which the patient must be regarded as infective. It has been suggested that

#### *The Significance of a Positive Reaction.*

a patient should be considered infective as long as the reaction remains positive. The serum diagnosis of tuberculosis presents peculiar difficulties. On the one hand it is generally believed that a large proportion of human beings incur at one time or another a tuberculous infection, on the other hand there are reasons for thinking that antibodies are not always or very readily formed as a sequel to infection by the tubercle bacillus. At any rate, it has been held that tuberculosis may be diagnosed by the recognition of antibody deficiency in the blood of the patient. A low opsonic index was very generally considered in the therapeutic use of tuberculosis, was an increased interest in the tuberculin test, and subsequently, when such a test was clearly recognized, and subsequently, when the practical value of the Wassermann reaction had become established, a considerable stimulus was given to the efforts of those who aimed at a complement fixation reaction for the diagnosis of tuberculosis. The possibilities of the complement fixation reaction for the diagnosis of tuberculosis have been in the minds of almost all serum workers since the time when Neisser and Sachs first turned this reaction to diagnostic use. In the early days of serum work the importance which would attach to such a test was clearly recognized, and subsequently, when the practical value of the Wassermann reaction had become established, a considerable stimulus was given to the efforts of those who aimed at a complement fixation reaction for the diagnosis of tuberculosis. The outcome of much work, of much more work than has come to publication, has been disappointing. It has been very generally assumed that one of the main difficulties lay in the preparation of a suitable suspension or extract of bacillary substances. But this technical difficulty of the bacillary extract may not be the only or even the chief difficulty. In the rainy days of the opsonic index it was claimed, and I presume the claim was well grounded, that many, perhaps a majority of, tuberculosis patients could be shown by the opsonic index method to be deficient in antibodies. The serum of such patients had, in fact, less opsonin than the serum of a healthy man. At the present time the complement fixation reaction is more popular, or at any rate is regarded as affording better prospects of success. But it would be surprising, I am disposed to think, if it was found that patients who could be diagnosed as tuberculous because their index was low could also be diagnosed as tuberculous because their serum gave a positive complement fixation reaction. In this connection and at this moment I am not writing you to believe, as I do believe, that both phagocytosis and complement fixation are controlled by a reaction taking place between antigen and one and the same kind of antibody. Even if you are convinced that specific opsonin is quite a different kind of antibody from the complement fixing antibody, it must still seem remarkable that tuberculous patients can be recognized by deficiency of the one and by superabundance of the other. Judged by the one reaction tuberculosis is to be suspected if the antibody content of the serum is below normal, judged by the other if the antibody content is above normal. From the above it would appear that our interpretation of the significance of a positive reaction is somewhat arbitrary and founded largely on the practical experience of different workers, using different reactions for the diagnosis of different diseases. The value of all this practical experience I do not for one moment question, but I think that we might have a better understanding of the relation between the production of antibody and the persistence in the body of the alien protein or antigen. It seems to me that the facts within our knowledge can be covered by an hypothesis which I venture to put forward for your consideration. The formation of specific antibody is induced by the introduction of the antigen into the animal body, is continued as long as the antigen persists in the tissues, and comes to an end when all traces of the antigen are destroyed. According to this hypothesis, the presence of antibody in a patient's serum, a positive serum reaction, is continued as long as the antigen persists in the tissues, and comes to an end when all traces of the antigen are destroyed. According to this hypothesis, the presence of antibody in a patient's serum, a positive serum reaction, is continued as long as the antigen persists in the tissues, and comes to an end when all traces of the antigen are destroyed. According to this hypothesis, the presence of antibody in a patient's serum, a positive serum reaction, is continued as long as the antigen persists in the tissues, and comes to an end when all traces of the antigen are destroyed.

**TYPES OF INFECTION.**

Two main types are met with—the one the lymphatic, the other the suppurative infection. The latter may be subdivided into that involving the cellular tissues of fingers and hand, and that involving mainly the tendon sheaths. Infection of bones or joints is almost always secondary and will be considered as a complication.

**Lymphatic Infection.**

This is given first place because it is the type of infection in which the life of the patient is seriously threatened. The infection, usually gaining entrance by a prick or scratch, leads within a few hours to a local congestion, associated with red lines up the arm, some swelling of the axillary lymph glands, and definite constitutional symptoms characterized by a rigor, rise of temperature, and malaise. The infecting organism is almost invariably the streptococcus, and the danger of septicaemia is a very real one. There should be little difficulty in distinguishing this type from the other infections of the hand. It is vital that a correct diagnosis should be made, as the treatment of such infection is altogether different from that of suppurating whitlow.

**Suppurative Cellulitis.**

This may occur in any part of the hand, but there are two situations where it is specially liable to arise and where its early recognition is particularly desirable. One is in the tip of the finger, where the dense, unyielding fibrous septa may confine pus under tension and lead to extensive necrosis of soft parts and bone. The other is deep in the palm of the hand, where, encased by the dense palmar fascia in front and by the bones and interossei muscles behind, the pus may accumulate under tension until, forcing its way along the lumbrical canals, it appears at the roots of the fingers. While such cellular tissue infection may extend to and involve the tendon sheaths, it may, and frequently does, occur independently—hence the importance of recognizing it and draining it along anatomical lines.

In passing one must refer to the infection so commonly met with in the nail-fold. Commencing as a cellulitis round the roof of the nail and discharging between the fold and the nail, this infection may spread under the nail and require its total or partial removal, but more frequently it is troublesome in that it leads to a chronic discharging sore under the fold, if not treated on rational lines.

**Tendon Sheath Infection.**

This may begin as a primary infection of the sheath from a direct wound; more often, however, it is a complication of a lymphatic infection of a finger. In the early stages of infection the sheath fills with a turbid, glairy fluid which rapidly tends to assume the character of pus. Owing to the limited capacity for expansion the exudate rapidly accumulates under tension, which compromises the vitality of the serous lining and of the tendons enclosed within. An early rupture of the sheath might possibly save the tendons; more often, however, the latter necrose unless the infection be very mild or early surgical relief be given. In any case the injury of the serous lining is apt to be followed by fibrous adhesions, contracting the sheath and fixing it to the tendons within. The essential features of tendon sheath infection are the early development of tension and the precarious nutrition of the structures within the sheath.

**Bone and Joint Infection.**

Seldom primary, infection may, and often does, involve the phalanges and interphalangeal joints. The most frequent examples are the necrosis of the distal phalanx in finger pulp infection and the involvement of the first interphalangeal joint in cellulitis or tendon-sheath infection of a digit. The rapid destruction of the articular cartilage and the softening of the lateral ligaments determines a loss of function in the joint even should the infection subside.

**DIAGNOSIS.**

In no surgical condition is accurate diagnosis so essential for rational and successful treatment as it is in hand infections. For accuracy in diagnosis an intelligent knowledge of the pathology of such infections is indispensable.

In the first place we must decide which type of infection is present. Is it an acute lymph infection, not walled off but spreading by lymphatic paths and threatening dangerous septicaemia? The marked, constitutional disturbance, the slight local swelling, the red lines up the arm, will seldom leave us in doubt. Is the infection a suppurative one involving cellular spaces but sparing the tendon sheaths? If localized to the tip of the finger with tense and tender pulp we immediately suspect suppuration, enclosed in the dense tissue in front of the distal phalanx. If there is marked swelling of a finger and of the hand we must decide whether or no a tendon sheath is involved or whether the suppuration is limited to cellular planes. A slight prominence of the palm with marked oedema of the dorsum of the hand makes us immediately suspect suppuration in the middle palmar space, the more so if a swelling is appearing in the cleft between the fingers. The uniform swelling of the finger, the flexed position, the pain on passive extension, and the exquisite tenderness when pressure is made over the proximal part of the palmar aspect of the finger, will leave little doubt that the tendon sheath is involved. It may be that the latter picture is combined with that of palmar space infection, and we recognize that an infected tendon sheath has ruptured into the palm. The swelling on the dorsum of the hand is seldom more than oedema, and will always make us search for evidence of pus in front. In the case of the thumb and little finger we may find the swelling extending to the wrist and forearm and we examine for evidence of suppuration in the radial or ulnar bursae, and possible extension to the deep cellular planes of the forearm into which the pus may have broken through. Finally, we determine whether there be signs of bone or joint involvement.

**TREATMENT.**

The worst infections of the hand usually start from small and trifling lesions, hence the importance of prophylaxis in the shape of prompt antiseptic dressing of all wounds in factories, workshops, and other centres of organized industry. For infections already established certain principles apply to infections of the hand:

1. Nature's effort to localize and restrict the spread of the infection must be aided and not combated.
2. Where the products of bacterial activity and tissue-cell death accumulate under tension, relief must be given by incision at the earliest possible moment.
3. Where spreading suppuration is present large incisions allowing of free drainage will cause less disability than smaller incisions with more protracted suppuration.
4. Rest to an inflamed part is an important factor in aiding speedy localization and resolution.
5. In a member such as the hand function means mobility, which, in its turn, depends on the smooth working of joints and gliding of tendons within their sheaths. While the first principle in treatment will therefore be the rapid arrest and localization of infection, this must be effected with the minimum of interference with the subsequent mobility and functional usefulness of the hand.

**Treatment of Acute Lymphatic Infection.**

No incision must ever be made at the point of infection in such a case during the early stages. Premature incision will increase the risk of septicaemia tenfold by opening up pathways which Nature is endeavouring to shut off by a leucocytic barrier. The principles of treatment must be to diminish absorption, to aid local resistance, to combat toxæmia, and, if possible, to give passive immunity. We encourage, therefore, hyperæmia locally by moist, hot applications, produce passive hyperæmia and delay absorption by applying Bier's elastic bandage to the upper arm, give fluid in large quantities by the mouth or rectum, and inject a large dose (50 c.cm.) of polyvalent antistreptococcal serum subcutaneously.

Considerable difference of opinion exists as to the value of Bier's congestion in hand infections. There can be no question, however, about its value in the acute lymphatic type of infection. I should put it first among therapeutic measures. Similarly, in regard to antistreptococcal serum, many are sceptical as to its value. My own experience has been that in many of these cases it gives great help, and

and after the attack of serum sickness. In one or two cases it seemed as if the attack of serum sickness was by a sharp fall in the amount of free antigen in the blood. At any rate free antigen could be demonstrated weeks after the attack of serum sickness and prevented to act within the patient's body as a stimulus to the further production of antibodies. If we admit that antigen may persist for a very long after it has been injected the experiment of Wassermann and Citron assumes a very considerable importance, the bacilli to other parts of the body by putting a rabbit's ear and endeavoured to prevent the transmission. The bacilli followed by a sharp drop in antibody content of the rabbit's serum. This experiment seems to show that if the antigen can be removed, the production of antibodies will be hindered or of a more indirect kind is afforded. After the first year of the war the prophylactic tetanus antitoxin was so successfully enforced that all wounded men received at least one and often four prophylactic injections of serum. Nevertheless, of late tetanus did occur and occasionally were of a severe nature. In these severe cases I was in the injecting a large dose of serum in a vein. In some cases of tetanus the intravenous injection, but in some patients the intravenous injection followed within a few minutes by the appearance of generalized tetania. In other cases there was a spread, but one or more isolated whisks appeared in a few seconds and no other changes, corresponding to the belief, occurring at the actual site of the subcutaneous prophylactic injections. These localized reactions occurring at the site of the prophylactic injections can be explained by the existence of the antigen and limited focus of antitoxin formation. I am inclined to believe that the production of antitoxin is ordinarily injected in the subcutaneous tissue and is not absorbed into the blood stream, but that the antigen is absorbed into the blood stream and is not absorbed into the blood stream.

• Λειτουργία 30

reactions, and, moreover, it is possible to put forward some small amount of evidence in support. If we wish to study the relations between the persistence of antigens and the production of antibodies we shall do so by the use, as antigens, of living bacteria which may multiply in the body subsequent to injection. For no number of antigen suspensions of dead bacteria, of which the size of doses may be estimated, is more suitable. If the horse appears to be such an antigen we may be observed by taking daily samples of the rabbit's blood, which are tested for the precipitation or more conveniently by the complement fixation reaction. If the daily sample is tested for the presence of both antigens and antibodies we can obtain daily records of the presence of both in the blood of the animal. Records of this type have been carried out by uninjected and others. In the course of such an experiment antibodies may be first demonstrable on about the fifth day after the injection. Subsequently, and for as long a period as the presence of the antigen can be demonstrated, it is found that antigen and antibody coexist in the blood. Although it was able to demonstrate the persistence of free antigen for fifteen days after its injection. During the war I had the opportunity of carrying out similar tests on soldiers to whom I had given large intravenous doses of tetanus antitoxin. In severe cases of tetanus I have often injected as much as 120 c.c. of serum into a vein. From some of these cases I collected weekly samples of blood and tested the resulting serum for free horse serum. In one case horse serum was still present on the forty-fourth day after the injection and in several other cases it had not disappeared after three or four weeks.

The persistence of free antigen for these long periods seems to me a matter of some importance, and it seems reasonable to suppose that traces of antigen may persist for much longer periods than it is possible to prove by the methods in the same specimen of blood is, of course, well known and can be readily demonstrated. Moreover, it is easily samples be taken from a rabbit after an injection of horse serum it will be observed not infrequently that on or about the eighth day the serum, which may be quite clear when first separated from the clot, throws down a precipitate. Spontaneous precipitation by the interaction of the free antigen and antibody which it contains. The formation of this spontaneous precipitation may be hastened by diluting the serum with saline solution. The effect of dilution and the fact that in the undiluted serum the precipitation forms but slowly suggests that under the conditions which prevail in the circulating blood the interaction of antigen and antibody with the blood vessels is usually in some fashion reversed. In a fatal case of anaphylactic shock following a fourth prophylactic injection of tetanus antitoxin, which I investigated some years ago, the specimen of serum obtained from the heart blood did show a spontaneous precipitation on standing. This precipitation formed in the separated serum and it formed some twenty-four hours after the patient's death. Death was not due to the formation of a precipitate during life. In the patient's blood, but it is of interest to note that he died of anaphylactic shock at the time when antigen and antibody were present in his blood in such relative proportions that a precipitate formed in
